SOME OBSERVATIONS ON CONGENITAL AND ACQUIRED HEMOLYTIC ICTERUS.

WITH A REPORT OF TWO CASES TREATED BY SPLENECTOMY.*

BY GEORGE EMERSON BREWER, M.D.,

NEW YORK.

THE object of this communication is to report two cases of splenomegalic hemolytic icterus, greatly improved if not cured by splenectomy.

Before describing in detail these two cases, it might be of value briefly to review a few facts which have contributed to our knowledge of this interesting condition.

During the past two decades a large amount of study, both clinical and pathological, has been expended on that interesting group of diseases associated with splenomegaly. Of these, three types, having a number of features in common, have perhaps received the most attention.

The first of these is that condition described many years ago by Banti, in which enlargement of the spleen is noted without other symptoms, often for a period of several years. Later there occurs a progressively increasing anemia of the chlorotic type, with gastric hemorrhages and still later evidences of cirrhosis of the liver, ascites, great weakness, emaciation, pigmentation of the skin, and death. To this condition the terms idopathic splenomegaly, splenic anemia, and Banti's disease have been applied.

The second of these conditions is that in which the splenomegaly is associated with a grave and progressive anemia. The disease advances much more rapidly than the former type, and always in the later stages presents the characteristic blood changes of pernicious anemia. In this type also, when untreated, the prognosis is fatal.

In the third type, the chief symptom is jaundice. The disease which may be congenital or acquired is an exceedingly chronic one, the jaundice often appearing at or shortly after birth, and may continue with certain variations in intensity throughout life. The jaundice in this condition has nothing to do with biliary obstruction or bile absorption, but is caused by a too rapid destruction of the red blood corpuscles and is in fact a true hemolytic icterus. The prognosis in this condition is much more favorable than in the first and second types, for a number of cases are on record in which a congenital jaundice has been present throughout a long life without causing marked impairment of health. In perhaps the majority of instances, however, of both the congenital and the acquired types, symptoms sooner or later appear which may result in chronic invalidism or even death.

While these three types of disease when observed in typical cases are quite different and distinct from each other, cases are not infrequently encountered in which they seem to be combined, as evidenced by a comparatively large number of observations in which a long observed hemolytic jaundice finaly presented the characteristic symptoms and blood picture of a pernicious anemia, or in which a definite pernicious anemia with splenomegaly was later associated with gastric hemorrhages or cirrhosis of the liver. These facts and the additional fact that in all three, we have splenomegaly, excessive hemolysis, anemia, and pigmentation would lead to the inquiry as to whether we are dealing with a single pathological entity, with variations in its symptomatology, or whether on the other hand these three conditions should be regarded as three definite and distinct diseases. This question has not up to the present time been definitely settled.

The essential features of splenomegalic hemolytic icterus are chronic jaundice and enlargement of the spleen. The jaundice is of a bright lemon yellow color, which varies in intensity, but is seldom if ever wholly absent. It is not associated with itching, torpor, slow pulse, or other evidences of intoxication with bile salts. The stools are never clay colored, but are light or dark brown, always showing an abundance of bile elements. The urine varies in color and contains urobilin. In some instances hemoglobinuria may be present. In most but not all cases there is a definite fragility of the red cells to the action of hypotonic salt solutions. Enlargement of the spleen is always present, and in the later stages of the disease may reach an enormous size.

In the congenital cases, the jaundice appears at or soon after birth. At first it is only a slight sallowness or yellow discoloration of the sclerotics, with a fainter color in the skin. As a rule there are no other symptoms, and the child may reach adolescence without or with but slight impairment to health. In other cases the child is never robust, the jaundice becomes more pronounced, the appetite is capricious, there are minor digestive disturbances, and anemia of the chlorotic type appears. The degree of anemia is often in direct proportion to the degree of the jaundice; and in the remissions in the intensity of the icterus, which are frequent, the general health and bodily vigor improve. In a fair number of congenital cases the individuals live to a ripe old age without serious inconvenience or ill health.

In the acquired cases, the jaundice is first observed during adolescence or early adult life, and while a fair proportion of these may continue for years without other marked symptoms, in the ma-

*Read at a meeting of the Pracitioners' Society, May 5, 1916.

jority of the acquired cases and in many of the congenital type there occurs sooner or later a series of febrile attacks or crises, in which there may be chills, elevation of temperature, pain in the upper abdomen, particularly on the left side, and tenderness of the spleen on palpation. With these symptoms there is general malaise with weakness, and an increase in the jaundice. Nausea and vomiting may occur, occasionally diarrhea and severe prostration. During these attacks there is an increased excretion of urobilin, and the urine may become blood red (hemoglobinuria). After each of these attacks the patient appears more anemic, and if the attacks are of frequent occurrence, the health rapidly declines. In a few recorded cases the anemia, which at first is always of the chlorotic type, gradually changes to the pernicious variety, and in these cases if untreated the prognosis is fatal.

While a definite enlargement of the spleen is always present when the disease is sufficiently advanced to admit of a positive diagnosis, in many cases it is overlooked, unless the left upper quadrant pain and tenderness or febrile crises lead to a careful physical examination. As a rule, the acquired cases progress more rapidly and are associated with more severe crises and a graver degree of anemia.

An interesting feature of the disease is its tendency to appear in several members of the same family. Graf reports a family of thirteen children, in which the father and six of the children suffered from the disease. Elliott and Kannavel report one family in which three cases occurred, and another in which four were jaundiced. In one of these the tendency was evidently inherited from the maternal great grandfather, six cases occurring in the second generation, seven in the third, and two in the fourth. The number of instances in which this family tendency has been observed has led to the general employment of the term familial hemolytic jaundice, as descriptive of this condition.

Regarding the etiology of the disease it may be stated that it is due to an exaggerated activity of the normal hemolytic function. While Chauffard and Widal have advanced the theory that the hemolyzing agents were present or at least primarily active in the blood and that the condition therefore was a true blood disease, most observers now hold to the opinion that the seat of the disease is the spleen. This view is based upon the fact that in these cases there is always present marked structural changes in this organ, and that careful microscopical and chemical examinations always reveal the evidences of excessive hemolysis in the spleen with the presence of a great excess of pigment granules showing the iron reaction, not only in the liver but in the tissues of the spleen and in the sinuses and tributaries of the splenic vein. These facts and the demonstrated curative effect of splenectomy leave little doubt as to the splenic origin of the symptoms.

Eppinger states that the condition may be spoken of as "hypersplenism," that while in these cases there is at all times an exaggeration of the normal hemolytic action of the spleen, there occurs from time to time a "massive hemolytic activity" with excessive destruction of the red cells, leading to the increased jaundice, anemia, and symptoms of acute intoxication.

In regard to the pathological changes in the spleen in this disease, a large number of observations have been published. While most of these simply report on the gross changes, a not inconsiderable number have recorded the results of careful and painstaking microscopic study. Among these may be mentioned those of Guizzetti, Micheli, Merkel, Kumpiess, Elliott, and Kannavel. In all of these, there is substantial agreement on the chief pathological changes in the splenic tissues, although the individual spleens show considerable variation in the extent and distribution of the lesions. Grossly the spleens show marked hypertrophy, hyperemia, a diminution in the number and size of the Malpighian follicles, and in some instances, thickening of the capsule and adhesions to the diaphragm and abdominal wall.

On microscopic examination the intense blood engorgment of the organ is found to be chiefly in the interstices of the splenic pulp, or the so-called strands of Billroth, the sinuses being nearly empty. The endothelial cells of the sinuses are greatly reduced in size and are oval rather than rod-shaped, as seen in normal spleens. The pulp arteries are occasionally surrounded by fibrous rings in a state of hyaline degeneration, and in their fibrous coats as well as in the surrounding fibrous tissue, are numerous pigment granules. Phagocytosis is marked particularly in the sinuses. Many of the red cells exhibit an irregular outline and show a diminished staining reaction to eosin. Many of the follicles are atrophied or totally degenerated. As certain of the changes in the spleen give evidence of the presence of a chronic inflammatory process, it is interesting to note that in a culture taken from a removed spleen and reported by Upcott and Gibson, a growth was obtained of an organism of the streptothrix group. Bunting has also obtained an organism of the diphtheroid group. Chauffard's report of three cases in one family, in which the Wassermann reaction was positive, and of three other patients in which positive signs of tuberculosis were present, led Kumpiess to make a critical analysis of seventy-nine cases of hemolytic jaundice, in which he was able to establish the association with syphilis in twelve, and of tuberculosis in five cases.

To sum up the facts so far observed in regard to the etiology, it may be stated that the disease is primarily due to an exaggeration of the normal hemolytic processes of the spleen and possibly other tissues of the body; that this excessive hemolytic activity is in all probability chiefly due to pathological changes in the spleen, and that there is some reason to believe that these changes may be the result of one or more types of chronic infection.

In regard to treatment, Banti was probably the first to employ splenectomy in the treatment of this condition. His patient, a woman fifty years of age, had suffered from severe anemia with tenderness in the hypochrondriac region for twenty-five years. Nine years before she came under observation hemolytic icterus developed and persisted until February 20, 1903, when Banti removed the spleen. She made a prompt recovery. She was examined eight years later, in 1911, and was found to be well with no evidence either of icterus or anemia.

In a paper by Muhsam in 1914 (*Deutsche med. Wochenschrift*, November 8, 1914), commenting on Banti's and a number of other cases in which splenectomy had been performed, he stated that he had personal knowledge that the operation had been employed for this condition in fourteen instances, and reports the results as remarkably favorable.

In a rather hasty and incomplete review of the current medical literature I have been able to find no less than thirty-one operations reported, prior

to 1915, with one operative death, and one death later from uremia.

Elliott and Kannavel have been more successful in their search, and in 1915, in an article in *Surgery, Gynecology, and Obstetrics*, they reported forty-eight operations with two deaths. Of these, nine were reported cured more than six months after operation. This list includes one by Spencer Wells twenty-seven years after operation, Banti's case eleven years, Bland Sutton's ten years, and a case reported by Roth six years. They also reported on a number of cases in which postoperative blood examinations were made as follows: Seven cases during the first two weeks, in which four had gained from one to two million red cells; eight cases examined from three to four weeks after operation, in which one gained over three million cells; two over two million, and three over one million. Nine cases reported examined from three to six months, with one case showing an increase of five million, four cases an increase of over three million, and five cases over one million.

While there are as yet very few reports stating the remote results of splenectomy in these cases, the records as far as they go show conclusively that in early splenectomy we have a comparatively safe and the only successful method yet suggested in the treatment of splenomegalic hemolytic icterus.

The following two cases have recently come under the writer's observation and treatment:

Case I.—C. L. A trained nurse aged 30 years. Has suffered from jaundice for seventeen years. Several members of mother's family have suffered from unexplained jaundice. During the first years practically no symptoms. From 1899, however, she experienced a number of attacks of moderate abdominal pain with anorexia, constipation, and increased jaundice. In the intervals the jaundice would lighten but it never disappeared. In 1904 she had a rather severe attack with markedly increased icterus, after which she was weak and indisposed for three months. In June, 1906, operated upon for epigastric pain and jaundice. Gallbladder found normal, easily emptied, no stones. Following this operation she was free from jaundice for two months, gradually regained her health and strength. After a few days of work in the autumn she had another attack of abdominal pain with jaundice. Several months later following another attack she underwent a second operation. Several small stones found. Gallbladder drained for twelve days. Jaundice decreased but did not wholly disappear. During 1908 and 1909, she experienced several more or less severe attacks of pain; one with jaundice, sour vomiting, and diarrhea, but without clay-colored stools, and another with some pain radiating to the right shoulder. Later she entered a hospital for severe diarrhea lasting ten days. These symptoms continued for the next five years, pain, nausea, fever, diarrhea, and a varying jaundice. Was finally seen by Dr. Lewis A. Conner, who made the diagnosis of familial hemolytic jaundice. Entered the Presbyterian Hospital October 8, 1915. On admission she was slightly jaundiced. Physical examination showed chest negative; abdomen; enlargement of the spleen, its anterior border being easily palpated for one or two inches below the costal border. Stools, brown color, contained urobilin. Urine negative. Blood coagulation time, seven minutes. White cells, 11,800; polynuclear, 78 per cent.; red cells, 3,408,000; hemoglobin, 75 per cent.; hemolysis test: Hemolysis begins at .375, complete at .350. Wassermann negative. October 23. Splenectomy; operation without difficulty and without shock. October 30. White cells, 31,000; polynuclears, 88 per cent. Novembr 1. Stitches removed, wound healed, primary union. November 11. Red cells, 4,216,000; white cells, 11,000; polynuclears, 80 per cent.; hemoglobin, 85 per cent. November 14. Hemolysis test: .550—.400. Discharged almost free from jaundice, gain of nearly 1,000,000 red cells and 10 per cent. in hemoglobin. May 2, six months and nine days after operation, fragility test shows hemolysis index .489; hemoglobin, 75 per cent.; red blood cells, 4,800,000; white cells, 13,400; polynuclears, 44 per cent.; lymphocytes, 54 per cent.; blood cholesterin, 3.61 grams to liter.

Case II.—H. O'S. 21. Referred by Dr. Schulman. No family history of jaundice. Three years ago noticed gradual onset of jaundice with lassitude, but without pain or other symptoms. Gradually grew weaker, suffered from occasional pains in upper abdomen, anorexia, and constipation. Lost fifteen pounds in past six weeks. Admitted to the Presbyterian Hospital service of Dr. Longcope. November 18, 1915. Sclerotics jaundiced, skin of face pigmentated in patches. Chest normal. Abdomen: spleen enlarged, anterior border easily palpated one inch below costal border. Blood examination: Red cells, 3,064,000; hemoglobin, 70 per cent.; whites, 9,500; polynuclears, 89.5 per cent.; lymphocytes, 10 per cent. Fragility test: Hemolysis begins at .425, complete at .4. Wassermann negative. November 22. Hemoglobin, 60 per cent. Vital stain: Reticulated cells, 27 per cent. Stools brown, no food remains, acid, no blood, urobilin marked. Urine negative. December 4. Splenectomy without difficulty or marked shock. Recovered from anesthetic satisfactorily. On second and third days suffered from postoperative gastric dilatation which, however, yielded to lavage and hot stupes. Primary union of wound, stitches removed on eighth day. December 18. Fragility test, .489-.483; red cells, 3,824,000; hemoglobin, 75 per cent.; white cells, 13,500; polynuclears, 68 per cent. December 21 Jaundice gone, pigmentation improving. May 2, five months after operation, fragility test, .595; hemoglobin, 80 per cent.; red blood cells, 4,900,000; white cells, 15,000; polynuclears, 54 per cent.; lymphocytes, 46 per cent.; blood cholesterin, 2.77 grams to liter; vital stain reticulated cells, 5 per cent.

Both patients are free from jaundice, are much improved in health, and are able to do their work without fatigue.

16 East Sixty-fourth Street.

THE HUMAN PROSTATE GLAND IN MIDDLE AGE.

By OSWALD S. LOWSLEY, A.B., M.D.,

NEW YORK.

The changes observed in the human prostate gland during the period of youth have already been considered and a review of the anatomical conditions existing during the adult stage, through the middle-age period, and up to the time of old age are now to be described.

By the beginning of the third decade the prostate has about reached its maximum growth so it is observed that practically the entire increase in size occurs during the second decade. Measurements in gross of specimens removed from subjects varying in age from twenty-one to thirty, disclose the fact that such glands vary in length between 2.8 cm. and 4.0 cm. The average being 3.3 cm. In width the smallest one measures 3.6 cm. while the largest is 5.2 cm., with an average of 4.16 cm. In thickness the dimensions are always less than the other two in this period. In this group it varies from 2.0 cm. to 3.0 cm., with an average of 2.4 cm. for all specimens. The trigonum vesicæ, which is generally presumed to be symmetrical, shows some asymmetry in over 50 per cent. of the cases studied. Extending between the apex of the trigonum and the upper end of the verumontanum there are always found small bands of tissue which vary in number from one or two to five. In this series 66 per cent. of the cases show one band only, in 14 per cent. there are two, and in 20 per cent. there are three. The verumontanum averages 2.0 cm. in length for all cases, while it is 0.41 cm. in width and 0.3 cm. in height. The mouth of the utricle varies somewhat in size, but it averages about 0.17 cm. The average depth of the lumen of the utricle is 0.5 cm., but there is a variation in this measure-

ment from 0.1 cm. to 0.7 cm.; 45 per cent. of the cases show an asymmetry in the seminal vesicles of considerable degree. The structures vary in length from 2.3 cm. to 4.4 cm., the average being 3.45 cm. In width the average measurement is 1.34 cm., thickness averages 0.78 cm.

Serial cross sections of a prostate taken from a man aged twenty-five shows the same general arrangement which characterizes the seventeen-year-old specimen described. There is noted a very slight increase in the size of the gland itself and of the individual tubules. The five lobes which make up the gland embryologically are distinguishable and the posterior lobe is fairly well separated from the remainder of the gland. The tubules of Albarran and the subtrigonal group are both present. The verumontanum containing utricle and orifices of ejaculatory ducts is about the average size for this decade. Seminal vesicles and ejaculatory ducts show the same general characteristics that have been described. The interesting group of tubules occurring on the ventral wall of the urethra at the apex of the prostate is present in this specimen.

Serial cross sections of a prostate gland and contiguous structures taken from a man thirty-four years of age show the following: *The middle lobe* is made up of seven tubules. They extend back to the very base of the prostate at which point their separation from the other lobes is pronounced. There it is observed that each branch of every tubule is surrounded by a fairly thick muscular wall which is composed of two distinct layers. The entire tubule in turn is surrounded by an even thicker sheet and a remarkable number of branches join and empty their contents into the prostatic urethra through a comparatively small duct. At the thickest portion of the middle lobe one cannot at a glance distinguish the dividing point between middle and lateral lobes. However, by observing the arrangement of tubules from section to section the division is quite apparent. As the ejaculatory ducts and utriculus prostaticus, surrounded by their thick muscular wall, assume their position in the gland just above the verumontanum, the ducts of the middle lobe tubules group themselves outside of the ventral surface of the above-mentioned muscular wall. At this point they are widely separated from all other portions of the gland, and there is a very definite layer of muscle and elastic tissue separating them from Albarran's group. The ducts open into the prostatic portion of the urethra near the upper borders of the lateral walls and the summit of the verumontanum. Their mouths are considerably separated from other structures and conform in this regard to their original embryological arrangement. It is noted that middle-lobe tubules are somewhat smaller than those of the lateral lobes and have not nearly so many branches. There has not thus far, with the methods at hand, been found a difference in the character of the mucosa. The general architectural characteristics correspond to a certain degree in all of the lobes. There are no particularly large intralobular blood vessels in this specimen.

The lateral lobes of this gland are large and bulging. They compose the main bulk of the organ and are particularly marked by the increase in the size of the tubules composing them and the large number of branches when compared with the younger specimens. There seems to be an increase in the amount of interstitial tissue present and large bundles of muscle fibers are observed at the upper and lateral margins. The capsule is fairly thick, and contains most of the large blood vessels. It is an interesting fact that while there are some blood vessels within the layers of the capsule on its posterior surface, the major portion of them are observed on the anterior aspect. The vessels that extend into the gland tissue proper seem to be quite small, as a general rule. The tubules composing the left lateral lobe are eleven in number while there are fifteen on the right side. It is noticed that the branches of these tubules practically all occur at the outer one-third of the lobe while the inner two-thirds or that portion which is nearest the urethra is composed mainly of muscular, elastic, and fibrous tissue elements. These proportions do not hold in the case of the posterior lobe although the general principle does. Most of the ducts of the lateral lobes have their orifices below the openings of the ejaculatory ducts, very few indeed being found above this point. The ducts proper are quite short and run almost at right angles to the axis of the urethra until the paraurethral region is approached, at which point they gradually bend toward the lumen and empty into it obliquely. The area through which the ducts pass, as described above, is composed of muscular and elastic tissue chiefly and the ducts themselves are surrounded by moderately thick, firmly bound muscular tunics. The entire anatomical arrangement gives one the impression that they are particularly arranged for a very rapid and complete emptying of any fluid within their lumina. The mouths of the ducts empty into the urethra at an angle in such a manner that there is a very thin laplet of tissue covering them so that in wide distention of the posterior urethra pressure would easily close their orifices very effectively, particularly as a large majority of them empty on the lateral walls of the verumontanum, which is itself an easily compressible organ. On the other hand, however, a number of them open directly into the bottom of the prostatic furrow and an effective closure of such duct openings would not be accomplished.

The posterior lobe extends from its origin on the floor of the urethra anteriorly or outward from the orifices of the ejaculatory ducts behind them to the point where they enter the prostate. This lobe is fairly well separated, in this specimen, from the lateral lobes by a layer of tissue similar in structure to the capsule of the gland. The tubules which compose this portion are eleven in number. They are large and have numerous branches. Their ducts are somewhat shorter than lateral lobe tubules in most instances. In this specimen many corpora amylacea occur in the posterior lobe tubules as well as in those of the middle and lateral lobes. The branches are more numerous near the periphery as is the case with the lateral lobes. The mucous membrane of the tubules is made up of the usual cylindrical cells with the nuclei at their bases resting upon a mattress composed of delicate connective tissue threads surrounding which are quite thick, dense layers of smooth muscle fibers. The lumina are widely distended, and contain secretion in most instances.

The anterior lobe. There are four very small tubules which have grown from the anterior wall of the urethra. These structures have few branches, are small in size, and insignificant in appearance. They occur at about the middle of the prostatic urethra. The lumina are lined with low columnar

epithelium, and there is no thick muscular layer surrounding them. The ducts are short and small, being about one-fifth the size of those of other parts of the gland.

The trigonum vesicæ is covered in practically every instance by a mucosa which is free from folds. In this instance there is a slight folding, over the middle portion of the trigonum. There are thirty-eight subtrigonal tubules in this specimen. They show a considerable increase in size over all of those previously described. This increase is noticed not only in regard to the extent of the tubules, but also there is an increase in the thickness of their walls, and, a most unusual thing, several of them have small branches. Although these interesting structures are considerably more extensive than in previously described younger specimens, they retain their general characteristics and grow down to the submucosa but not through it. Their blind ends are situated nearer to the base of the trigone than are their mouths, although they are in every instance very short. Thus their course is seen to be an oblique one. Their mouths open directly into the bladder lumen and are not in any sense protected by a valve-like membrane, as is the case with the duct openings of the prostatic tubules. There is nothing distinctive about the histological arrangement. There are several layers of low cylindrical and cuboidal cells disposed upon a tunica propia. In some instances the cells are piled upon one another, layer by layer, so that the lumen of the tubules is very small in size. No secretory substance can be made out within the lumina of these glands as is often the case with prostatic tubules. They vary considerably in size, some of the largest of them having a small branch but in no case was there found to be more than one, and never does the structure extend through the submucosa, although the ends of the tubule often extend to it.

Albarran's Tubules.—Thirty-one tubules of Albarran are found in the subcervical region of this specimen. They are larger and more branching than any of the younger specimens studied. The uppermost tubules of this large and interesting group of structures are found under the lower part of the trigonum vesicæ. At places it is observed that several subtrigonal glands occur in the mucosa and below them there are seen branches of Albarran's glands, which are embedded in the submucosa and in some places have extended slightly into the sphincteric muscle, but for the most part are contained within the circular fibers making up the sphincter, and in only a few instances do they mingle with these fibers. A very interesting arrangement is noted in that just above the lower border of the thick, ribbon-like internal sphincter and posterior to it there are a few of the branches of Albarran's tubules which are very delicate in architecture with no muscular walls and join with other branches of the same group below the border of the sphincter and empty into the urethra in about the middle line above the verumontanum. Thus we have some of the tubules of Albarran in the shape of a letter "Y" fitting over the lower border of the sphincter, a condition which has not been found in any of the other specimens studied. At no point do these tubules mingle with those of the middle lobe, being widely separated from them. The majority of the tubules composing this group empty on the floor of the urethra. Their branches are quite numerous, in some cases as many as fifteen being counted for one tubule. They always extend toward the bladder and are separated from other structures at the neck of that viscus. Most of them are suburethral but there are a few which empty into the urethra upon its lateral walls and one or two on its anterior wall. These glands are compound tubular and the mucosa is made up of low columnar cells of small size placed upon a thin connective tissue lining membrane. They are very frail, being much smaller in size than prostatic tubules and have no differentiated envelopes surrounding them.

The verumontanum in this specimen measures 0.4 cm. in height, 0.4 cm. in width and contains portions of some of the tubules of the prostate, the ejaculatory ducts and utricle with their surrounding structures.

The utrieulus prostaticus is quite large and deep in this specimen. It extends from its opening in the summit of the verumontanum almost to the base of the prostate, and is about 1.1 cm. in depth. In size it is about three times as large as either of the ejaculatory ducts, and is in a more or less collapsed condition, so that the mucous lining is markedly folded, the lumen proper being almost entirely filled by it. At its end, near the base of the prostate, it is surrounded by a very thick wall of muscular and connective tissue which is at least three times the size of the walls of the ejaculatory ducts. The three structures, each surrounded by its own distinctive wall, are bound together by a comparatively thin envelope which contains them all. At a point about midway between the base of the prostate and the upper end of the verumontanum the individual walls of the ejaculatory ducts and utricle are not so thick as is the case nearer the base, but the envelope surrounding them becomes much more prominent and is arranged far more compactly. This firmly bound structure maintains its compactness until it reaches the verumontanum, at which point the utricle changes markedly in appearance. It is smaller in size and surrounding it almost completely are a great many tubular structures which have in most instances a few branches. They are lined by a mucous membrane similar in type to that of the utricle itself and in turn have a rather thin wall of differentiated tissue surrounding them. Most of these glandular structures enter the utricle itself, but a number of them, near its orifice, open directly into the lumen of the urethra on the summit of the verumontanum and close to the orifice. As is usually the case, the orifice of the utriculus prostaticus opens in the midline just a little outerward from the openings of the ejaculatory ducts.

The vasa deferentia are unusual in a number of ways. The mucosa is very thick and much folded, thus making the lumen quite small. The walls are about four times as thick as the diameter of the lumen and mucous layers and are composed of white fibrous connective tissue and smooth muscle fibers very compactly arranged. At intervals there are found, imbedded in this thick wall, small simple tubules which communicate with the lumina of the ducts. Some of these tubules extend quite deeply into the walls. At the region of the ampullæ of the vasa deferentia the lumina are increased in diameter about five times and the walls are, comparatively speaking, much decreased in thickness. There are a number of folds in the ampulla which afford an added capacity. Towards the urethra, where the vasa deferentia become imbedded in the

tissue of the prostate, they decrease in size until they are a trifle smaller than above the region of the ampullæ. No accessory tubules are noted in their walls at this point.

Well within the base of the prostate the ducts of the seminal vesicles unite with the vasa deferentia to form the ejaculatory ducts. The seminal vesicles themselves extend backward so that their highest level is farther than the base of the trigonum vesicæ. They are made up of a main lumen and several large convoluted branches on each side and are bound together and to the vasa deferentia by a triple-layered fascia which I have described in detail in another communication. The ejaculatory ducts become gradually smaller in size and approach each other more closely as they extend in a rather oblique direction at first and then quite perpendicularly to a location in the summit of the verumontanum, at which point they turn sharply and run parallel with the axis of the urethra for about 0.5 cm., where they open laterally into the urethra near the summit of the verumontanum.

The apex group of glands is made up of nine small tubules with many branches all of which are contained within the wall of the membraneous urethra just at and below the apex of the prostate. These glands are compound tubular in type and for the most part are found extending from the floor of the urethra, although there are a few found laterally and an occasional one in the ventral wall.

During the fourth decade there is no particularly marked change in the gross measurements as compared with the prostates of the third decade at which time this organ seems to have reached its maximum adult size. The blood vessels, most of which are grouped in the anterior and lateral portions of the capsule, are somewhat larger, and phleboliths are more frequently found than in the case previously observed. In size the organs examined vary from 2.4 cm. to 4.0 cm. as regards their length, the average being 3.15 cm. In width, which is always the greatest dimension, there is a variance of from 3.0 cm. to 5.0 cm., the average of 4.0 cm. existing. Thickness averages 2.55 cm. The trigonæ vesicæ of all the specimens being carefully measured show that 50 per cent. of them are asymmetrical by over 0.4 cm. Extending between the apex of the trigonum vesicæ and the upper end of the verumontanum some of the cases have one band of tissue, a few have two, and in over one-half there are three such structures. In younger specimens its length varies at this age from 1.1 cm. to 2.6 cm. The average is 1.8 cm. The width and height, which are usually about the same, average 0.43 cm. in width and 0.46 cm. in height. The utricular orifices average 0.15 cm., the variation being from 0.1 cm. to 0.25 cm., while the length of this interesting vestigial organ varies from 0.2 cm. to 0.9 cm., with an average of 0.5 cm. The seminal vesicles are interesting in that there is a condition of asymmetry in about 60 per cent. of those measured at this age. They average 4.0 cm. in length, 1.1 cm. in width and 0.94 cm. in thickness.

In the fifth decade there is only the very slightest increase in size of the prostate compared with its measurements of the previous period. The average length is 3.45 cm., there being a variation of 1.6 cm. between the shortest and longest glands measured during this period; the former is 3.0 cm. and the latter 4.6 cm. The width, which is always greater, varies from 3.6 cm. to 5.0 cm., with an average of 4.0 cm. The average depth is 2.65 cm.; the variation being from 2.3 cm. to 3.8 cm.

Sixty per cent. of all of the specimens of this age at hand showed an asymmetry of the trigonum vesicæ of over 0.4 cm. The blood vessels in this portion of the bladder seem to become considerably more prominent during the middle and later years of life, and are quite conspicuous during this decade. The verumontanum is very slightly increased in length, the average being 1.95 cm., varying from 1.7 cm. to 2.7 cm. Its width averages 0.45 cm. and height 0.49 cm. The mouth of the utricle varies from 0.1 cm. to 0.4 cm., the average being 0.19 cm. The length or depth of this interesting structure varies from 0.3 cm. to 1.6 cm. The average is 0.7 cm. The average length of seminal vesicles is 3.9 cm., but the variation is very great. One specimen forty-seven years of age has vesicles which measure only 1.8 cm. Another at forty-eight years measures 5.0 cm. The average width and thickness are 1.66 cm. and 0.9 cm. respectively.

Dr. George Walker of Baltimore permitted me to study the prostate of a man who died at about the middle of the fifth decade, which had been cut in series and stained with hematoxylin and eosin. In general this series shows characteristics similar to those of organs already described.

The size of the prostate during the sixth decade is practically the same as that of the fourth and fifth decades. In length the average measurement is 3.65 cm., varying from 2.4 cm. to 4.5 cm. The average width is 4.37 cm., the least wide being 3.3 cm. and the greatest 5.0 cm. In thickness there is a variation of 1.0 cm., the average being 2.75 cm.

The trigonum vesicæ shows an asymmetry of over 0.4 cm. in 80 per cent. of the specimens. The verumontanum is about the same length as in the preceding period, the average being 1.7 cm. It is 0.43 cm. in width and the same in height. The mouths of the utricle average 0.13 cm. in length while the length of the utricle averages 0.7 cm., varying from 0.4 cm. to 1.3 cm. The seminal vesicles show very little change in size, averaging 3.7 cm. in length, 1.55 cm. in width and 0.8 cm. in thickness. Thirty per cent. of the seminal vesicles were asymmetrical comparing one side with the other.

The human prostate gland reaches its maximum size in health by the end of the third decade, almost the entire change occurring during the second period. The measurements for the adult organ as given by Wilson and McGrath agree fairly well with the measurements during the adult decades in my series. They found the average adult gland to vary in length from 3.3 cm. to 4.5 cm., with an average of 3.4 cm. In width there is a variation from 3.4 cm. to 4.5 cm., average 4.4 cm. Thickness varies from 1.3 cm. to 2.4 cm., averages 1.5 cm. The weight averages 16 or 17 grams. Cuthbert Wallace does not quite agree with these figures. He states the length to be 3.0 cm., the greatest transverse diameter being 3.6 cm. and the anteroposterior measurement 1.8 cm. He believes the average weight to be 20.5 grams. It seems to me to be much more preferable to consider the size of the gland in decades in order to detect the changes that may normally occur. Considering the matter in this manner with a moderately large number of specimens in each decade I have shown that the prostate practically reaches the maximum normal size during the third decade. During the fifth and

sixth decades the size is very slightly increased, but the change is very slight, as shown by the accompanying table.

Table Showing Changes in Size of the Prostate Gland at Various Ages in a Series of 224 Cases

Age	Number of Cases	Length		Width		Height	
		Variation	Average	Variation	Average	Variation	Average
1st decade, 1-10 years	38	1.0 cm. to 1.7 cm.	1.2 cm.	1.0 cm. to 2.0 cm.	1.5 cm.	0.7 cm. to 1.3 cm.	0.9 cm.
2d decade, 10-20 years	10	2.5 cm. to 3.5 cm.	3.0 cm.	.....	3.8 cm.	1.8 cm. to 2.4 cm.	2.1 cm.
3rd decade, 20-30 years	40	2.8 cm. to 4.0 cm.	3.3 cm.	3.6 cm. to 5.2 cm.	4.1 cm.	2.0 cm. to 3.0 cm.	2.4 cm.
4th decade, 30-40 years	33	2.4 cm. to 4.0 cm.	3.15 cm.	3.0 cm. to 5.0 cm.	4.1 cm.	1.6 cm. to 3.0 cm.	2.55 cm.
5th decade, 40-50 years	42	3.0 cm. to 4.6 cm.	3.45 cm.	3.6 cm. to 5.0 cm.	4.0 cm.	2.3 cm. to 3.8 cm.	2.65 cm.
6th decade, 50-60 years	29	2.4 cm. to 4.5 cm.	3.65 cm.	3.3 cm. to 5.0 cm.	4.37 cm.	2.4 cm. to 3.4 cm.	2.75 cm.
Old age, 60 years	32	2.6 cm. to 4.5 cm.	3.23 cm.	3.0 cm. to 5.0 cm.	4.12 cm.	2.0 cm. to 3.6 cm.	2.47 cm.

The prostate gland is in every instance divided into five portions corresponding to the five original groups of tubular evaginations noted in the embryo. The division between the middle and two lateral lobes becomes less and less noticeable as age advances, but the orifices of the middle lobe tubules are in every instance widely separated from all other tubular orifices and quite closely grouped together. The middle lobe tubules always grow backward behind the vesical orifice outside of the broad ribbon-like sphincter, and its tubules are never found imbedding themselves in it or extending within the sphincter. This is an important fact to be noted when considering pathological conditions at the bladder orifice, and will be discussed in another paper at a later date. The lateral lobes during the period of middle age become more and more prominent and cause a bulging of the lateral surfaces to a marked degree, thus making the transverse diameter of the organ proportionally greater than the prepuberty specimens studied. The number of branches of these and other lobes of the prostate are markedly increased but the number of tubules is certainly not increased and seems rather to be decreased, but that is a variable matter which is undoubtedly determined in the embryo, and the exact number is a personal characteristic.

The posterior lobe is fairly well separated from all of the other portions of the gland and is divided off by a rather firm, and in some instances, quite thick connective tissue partition. It is always present as is the lobe itself, and is intimately attached to the ejaculatory ducts which are not imbedded in this partition, but seem to be set upon its anterior surface. This is a decidedly important matter to the surgeon in enucleating a prostate either by Squier's suprapubic intraurethral method in which the enucleating finger approaches the partition and attached ejaculatory ducts and passes along to the upper end of the verumontanum, which is usually removed without injuring the ducts and surely would not be injured if the verumontanum, which is usually torn through with some difficulty, were cut with the scissors; or Young's perineal method in which the two parallel longitudinal incisions must be extended entirely through the partition, thus preserving the ejaculatory ducts in order that the enucleating instrument may go into the lateral lobe cavities because otherwise it will lead into the capsule of the gland and proper enucleation is then an impossibility.

The posterior lobe is always present and is the part of the gland felt per rectum. Its tubules are in most respects similar to those of the other lobes. In some cases, however, they seem not to be quite so large and in most instances there is evidence that they do not secrete prostatic fluid actively. The branches of these tubules are usually not as numerous as those of other lobes, and are smaller in size and have a thinner layer of smooth muscle surrounding them.

The anterior lobe varies greatly in different specimens. At the time of birth it consists of two small unimportant tubules with very few branches. In the post-puberty specimen the anterior lobe is quite prominent and is made up of tubules which branch extensively and are apparently actively secreting prostatic fluid. A number of important changes are noted when the pre-puberty prostates are compared with the gland in adult life. In order to study the various types of tissue, sections have been stained with Van Gieson's, hematoxylin and eosin, and Weigert's elastic tissue stains. The mucosa of the terminal branches of prostatic tubules in pre-puberty specimens is made up of cuboidal-shaped cells with nuclei which are quite large and situated in the center of the cells. They are usually two layers thick and occasionally three. Scattered here and there are occasional cylindrical-shaped cells with the nuclei elongated and in the center of the cell. The lumina are very small and apparently devoid of secretion. The mucous cells are placed upon a felt-like base made up of minute connective tissue fibers, as described by Walker. The smooth muscle layer surrounding the terminal branches are very interesting as brought out by Van Gieson's differential stain. Each branch is surrounded by a definite layer of smooth muscle circularly arranged. The branches occur in groups of 5 to 10, and the entire tubule is surrounded by a much heavier envelope of smooth muscle, also circularly arranged. Outside of this envelope there are several small bundles of longitudinal fibers which occur at intervals around the tubule but not as a definite intact sheet. The branches of tubules all extend backward towards the base of the prostate with the exception of a few of the most anterior tubules of the lateral and posterior lobes. The collecting ducts are situated at the most anterior portion of a given group of branches and pass quite directly toward the verumontanum so that almost the entire duct, with the exception of a very small portion which turns forward, may be seen in one cross section. The ducts are lined by a mucous membrane which resembles that already described in practically every detail. There is, however, a great difference noted in the arrangement of the musculature. A thick layer of smooth muscle surrounds the ducts, but it is arranged almost entirely in a longitudinal direction, very little circular muscle being noted. There are practically no branches from this portion of the tubule, most of them occuring in the peripheral third of the gland. In the verumontanum, the tubule turns and runs forward for a slight distance again, and

about nine-tenths of them open on the lateral walls of the verumontanum in such a manner that there is a little leaflet of tissue covering the orifice which is an exceedingly important factor in protecting the tubules of the gland from an inpouring of urine and other foreign matter when the posterior urethra is put under pressure. The direction of the openings of the tubules of the prostate and ejaculatory ducts is an important consideration also because instrumentation will frequently cause an infection by forcing foreign substances into them. In the adult prostate there is noted a great change in the mucosa. I have found in my specimens that the tubules and their branches are lined by a single layer of high cylindrical cells with the nuclei at their bases. Occasionally there is inserted, between the bases of adjoining cells, a round or conical cell, as Krause pointed out. In some places there is a piling up of the cylindrical cells, but I have not found that there is a double layer of cylindrical cells in all of the terminal branches as Langerhans states. Near the orifices of the ducts the epithelium is transitional in type, being similar to that of the urethra itself. The muscle bundles surrounding the tubular branches are very thick in the peripheral portions of the gland, and particularly in the case of middle-lobe tubules near its base. These muscular bundles are much more pronounced, comparatively speaking, in the case of the younger specimens than in the older, and this is probably due largely to the fact that the entire gland becomes more compactly arranged after puberty.

It is interesting to note the various figures quoted in regard to the prostatic tubules. By carefully following each tubule from its most peripheral terminal branches to the orifice from section to section, I have found that in twelve specimens studied, in this manner, the number of middle-lobe tubules vary from 0 to 12, with an average of ten. Right lateral lobe varies from 10 to 23, average 16. Left lateral lobe 11 to 23, average 16. Posterior lobe varies from 6 to 12, with an average of 9, and the anterior lobe from 2 to 14, averaging 7. The total number of tubules varies from 41 to 74, with an average in all specimens of 58. This figure is much greater than that quoted by most authors. Kölliker states that the number varies between thirty and fifty; Hessling 15 to 30; Luscha 16 to 25; Svetlin 15 to 32. I do not believe it possible to estimate the exact number of prostatic tubules by the examination of the posterior urethra by any method because of the interesting manner in which these tubules enter the urethra. In health they are rarely visible by using any posterior urethroscope, but in diseased conditions their orifices become indurated and in some cases are actually held widely open and can be seen beautifully with the McCarthy straight instrument.

The prostate gland seems in adult years to be made up of concentric layers of tissue. The innermost or central area consists of the horseshoe-shaped urethra with the verumontanum, which is made up of the ejaculatory ducts and utricle, with their muscular and connective-tissue walls, the terminal ends of the prostatic tubules with their rather thinly disposed circular layers of muscle, and the stroma, which is not very abundant and is made up of connective tissue for the most part with a moderate amount of smooth muscle fibers but practically no elastic tissue fibers. The next layer, in the lateral and posterior direction, is made up of stroma with practically no tubular tissue except the ducts proper, which have very few branches. The stroma is largely made up of connective tissue with a generous sprinkling of smooth muscle cells which are not arranged in definite

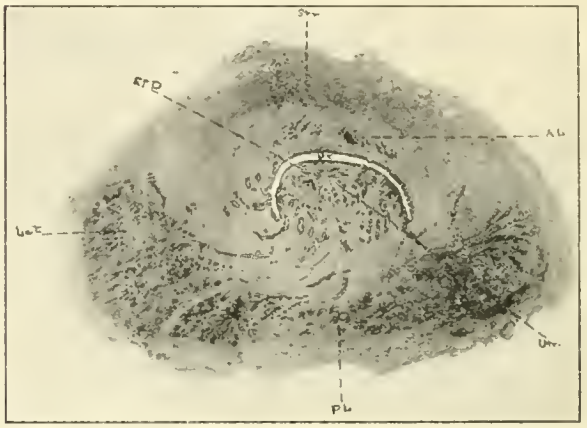

Fig. 1.—Cross-section through the prostate at the level of the openings of the ejaculatory ducts of a four year old child. *Ur*, urethra; *Ej.D*, ejaculatory ducts; *Utr*, region usually occupied by the utriculus prostaticus is in this case occupied by two tubules with many branches; *Str*, striated muscle in anterior portion of gland; *AL*, anterior lobe tubules; *Lat*, lateral lobe tubules; *PL*, posterior lobe tubules.

bundles except around the tubular ducts, as has already been described. There are a moderate number of elastic tissue fibers here also. In the anterior region there are observed the tubules of the anterior lobe with a very slight amount of smooth muscle around them quite firmly imbedded in the stroma. This consists in the anterior region of the middle concentric layer of a considerable amount of smooth muscular fibers interspersed with the white fibrous tissue bundles with occasional fibers of elastic tissue. Near the upper border of the layer are seen a few bundles of striated muscle fibers which in my specimens have not been found to exist among the tubular branches. Cuthbert Wallace, however, reports that he has observed them around some of the outermost of the branches of lateral lobe tubules. The outermost of these concentric layers is exceedingly interesting as it

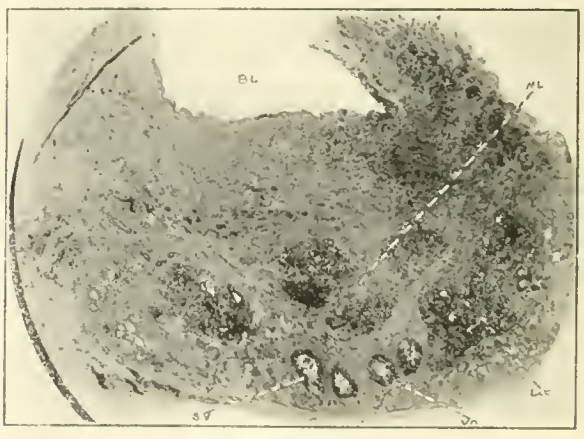

Fig. 2.—Cross-section through the region of the middle of the trigonum vesicæ of a man 34 years of age. *BL*, bladder lumen; *ML*, middle lobe tubules showing wide separation from the lateral lobes; *Lat*, lateral lobe tubules; *VD*, *vas deferens*; *SV*, seminal vesicle.

contains practically all the branches of the posterior and lateral lobes. The middle and anterior lobes are contained, for the most part, in the middle concentric layer. In the outer layer there is a great preponderance of muscular tissue and mucosa.

over all other elements of the gland. In the posterior and lateral portions the muscular tissue is practically all smooth and surrounds the tubular elements, as has been described. In the anterior portion and extending down the lateral borders al-

most to the posterior surface are found the striated fibers which make up the so-called muscle of Henle. This muscular tissue is so arranged that near the most anterior portion of the gland it is almost the only tissue present. Looking from this point toward the urethra it is seen to become less and less, gradually shading off and being scattered by the smooth muscle and connective tissue so that at the edge of the middle concentric layer there are only occasional fibers noted. There is less and less striated muscle down the lateral borders of the gland until it finally disappears altogether.

There are islands of lymphoid tissue scattered here and there in the adult prostates. Rarely one finds some of these areas in the pre-puberty specimens. They seem to be most frequently met with in specimens older than thirty years. Waldeyer has found similar areas in the prostate of a dog and Weski has studied them in the human and believes them to be normal anatomical structures.

The base of the prostate is intimately attached to the musculature of the bladder, as shown in Figs. 2 and 3.

In regard to the internal sphincter of the human bladder Versari concludes from his investigations that (1) The smooth muscle sphincter of the urinary bladder of man constitutes a structure by itself, which develops independently of the middle (circular) layer of the bladder, the circular muscle layer of the urethra, and the musculature of the ureters. (2) The sphincter is made up of an urethral and a trigonal portion, and it is the urethral portion only which assumes the form of a ring surrounding the initial part of the urethra. The first groups of the fibers of the sphincter arranged in bundles correspond to the anterior arch of the urethral portion; from there immediately follow those of the urethral portion of the posterior arch, and these last are apparently those of the trigonal portion. The posterior arch of muscle extends little by little, with new bundles either upwards to occupy part of the trigonal area or downwards along the posterior wall of the urethra, so that it comes to have an extent much greater than the anterior. On the other hand, the older view held by Krause, Hyrtl, Gegenbauer, and others is that the sphincter is a continuation downward of the circular musculature of the bladder.

The capsule of the prostate is composed of a structure which is made up of closely knit connective tissue fibers and surrounds the entire organ except at the base between the entrance of the ejaculatory ducts into the substance of the prostate and the junction of the bladder wall with the gland. Here the tubules of the middle lobe are almost free and have as a consequence very thick muscular and connective tissue walls. The large blood vessels which supply the prostate run in the capsule and intralobular partitions for the most part and are most numerous on the anterior portion of the capsule. By fibrous connections adhering to the capsule the prostate is fixed in position. Retzius has termed this the ligamentum pelvic-prostaticum capsulare.

A study of the secretion of the prostate gland in adults is very instructive. Normally it is milky in appearance, possesses a characteristic pungent odor, and is usually acid in reaction, but may be neutral. Under the microscope it is seen to be composed of a fluid containing numerous spherical refractile bodies of varying sizes composed of lecithin. There are very few leucocytes in normal cases and no erythrocytes. Spermatozoa are not usually found in fluid obtained by massage unless the vesicles are also touched. The relation between the lecithin bodies and leucocytes is an excellent indicator for determining whether the prostate is normal or the seat of inflammation. Cells composed of many refractile granules often brownish in color are found. These structures have been described by Waldeyer, who called them compound granular cells, and are found often after the fortieth year, and in most of the cases older than fifty. Corpora amylacea are occasionally met with. They have a slightly brownish color, as a rule, although they may be colorless. They are composed of concentric layers, and look more or less like an onion cut in cross section. They are found in old age most frequently but occur in younger specimens as well. I remember one specimen particularly, obtained from a man thirty-four years of age, which had more corpora amylacea than any other that I have seen. There are usually some loose epithelial cells

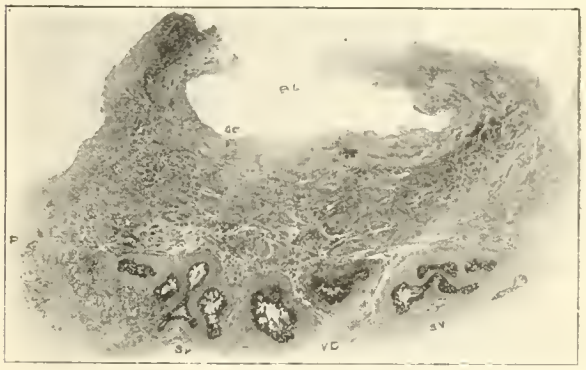

FIG. 4.—Cross-section through middle of trigonum vesicæ of 17 year-old boy. *BL*, bladder lumen; ST, subtrigonal tubule; *VD*, ampullæ of *vas diferentia*; *SV*, seminal vesicles; *P*, lateral lobe tubules of the prostate.

which have been exfoliated from the mucosa. Wilson and McGrath, in their splendid review of the literature of the prostate gland, have explained the various views on the chemistry and physiology of prostatic secretion.

There are a number of organs which are so intimately associated with the prostate gland that I have called them accessory structures. They occupy in each instance a position contiguous to this organ and a disturbance in their arrangement or function is of as much importance as a disturbance of the prostate itself. There is a member of this group of structures which I have described and called the subtrigonal group of tubules. They occur in the mucosa of the trigonum vesicæ usually below its central point, and are found as far outerward as the apex. They are for the most part simple tubules which extend to the submucosa and somewhat into it. In the younger specimens there are never branches, but some of those found during the middle-age period show one or two small branches. There is nothing distinctive about the structure of the membranes of the subtrigonal group. The mucous lining is composed of transitional epithelium similar in type to the vesical mucosa. The cells are much piled up and in some cases five or six deep. Their lumina are quite small, as a rule. These tubules are of importance on account of two facts. First, because their position is such that an overgrowth or enlargement from any cause will bring about a disturbance in the emptying of the bladder; second, because an enlargement of this group does occur in a small percentage of cases. I have observed six non-malignant tumors of the trigonum vesicæ intravitam and three in post-mortem specimens. The number of these simple finger-formed tubules increases markedly after birth but are found in the embryo after the fourth month. More than twenty of them are observed in every specimen older than four years.

Albarran's subcervical group is by far the most important structure at the orifice of the bladder. It is made up of many tubules which are rather frail in structure and whose ducts open in or near the midline of the floor of the urethra between the upper end of the verumontanum and the orifice of the bladder. As shown by Van Gieson's differential stain no smooth muscle fibers are demonstrable around these tubules, which are much more frail than the prostatic glandular elements. In every case studied with one exception these tubules and their branches grow entirely within the sphincter of the bladder, thus occupying a most important position. In the case of the thirty-four-year-old specimen a few branches of Albarran's tubules extend outside of the sphincter for a short distance. Up to the time of birth these tubules are few in number, but all specimens examined older than three years have more than thirty of them. Not only are the location and number of Albarran's tubules important, but for some reason pathological change in the form of enlargement in this region is very frequent. In my series of post-mortem specimens, I have found almost 25 per cent. of the specimens taken from men over thirty years of age to be enlarged sufficiently to demonstrate signs of obstruction in the bladder. It often happens that the passage of an instrument such as a catheter in a patient who is suffering from a moderate obstruction to urination will be completely obstructed thereafter. It seems to me that such trauma causes an edema of both the subtrigonal and Albarran's tubules, thereby producing a complete blocking of the upper end of the urethra.

The seminal vesicles and the lower portions of the vasa deferentia are bound together by a fascia which I have called the intervesicular fascia. It is made up of three portions, the most prominent being the posterior leaflet, which is composed of two layers. It extends around and between the two seminal vesicles and posterior to the vasa deferentia. The seminal vesicles are thus suspended in a sac-like structure, the posterior layer of which extends directly across from one vesicle to the other. The anterior layer, after circling the vesicles, joins the posterior lamella at the border of each vesicle and becomes intimately attached to it, thus forming a two-layered, rather firm fibrous fascia. The middle portion is formed by a two-layered structure which envelops the vasa deferentia in a similar manner. The third or anterior lamella is a single-layered fibrous structure extending from the anterior and lateral surfaces of one seminal vesicle to those of the other, at which point it is attached to the encircling portions of the posterior part of the fascia described above. In most instances the upper border of this fascia extends somewhat higher than the fascia of Denonvilliers, and the two structures are easily separated, being in direct contact only at the lateral surfaces of the seminal vesicles. At other places the two structures are separated by a considerable amount of fatty and areolar tissue.

The intervesicular fascia is not nearly so firm as that of Denonvilliers. Its posterior leaflet is the strongest portion; the middle, or that portion which encircles the vasa deferentia, is the weakest. The three lamellæ combined hold the seminal vesicles and vasa deferentia in a very definite envelope, which is of considerable importance in surgery of this region. This structure is undoubtedly a barrier to the extension of carcinoma, and may explain why carcinoma of the seminal vesicles is usually confined to those structures for such a long period of time without extension to surrounding tissues and organs. The type of pain which accompanies acute infections of the seminal vesicles is explained by the fact that these organs are contained within a sacculated fascia. The intervesicular fascia corresponds fairly well to the area of the trigonum vesicæ and, reinforced by the fascia of Denonvilliers, forms a firm support to the bladder wall at this area, and is an additional factor in preventing the formation of diverticula in this region.

The epithelium of the vasa deferentia is made up in part of simple ciliated columnar, and in part of stratified ciliated columnar cells, with two rows of cells. The cilia are often absent, however, and vary a great deal. In the ampulla of the vas deferens the epithelium is for the most part simple columnar in type and the cells often contain granules of yellow pigment. Besides folds there are evaginations and tubules which occur frequently in older specimens and extend quite deeply into the muscular walls. The epithelium of the seminal vesicles is simple nonciliated columnar in type containing yellow pigment.

The ejaculatory ducts as a rule are lined by a single layer of columnar cells, although the mucosa is often folded and the cells are frequently arranged in two or three layers. These structures usually remain attached to the upper surface of the partition separating the posterior from the lateral lobes and pass through the prostate as a distinct body until they arrive at the verumontanum, where their muscular walls become quite thin and less compact, and while they are arranged circularly, as Porosz described, they are so frail that their sphincteric ac-

tion must be very slight. Their main protective agent seems to be the fact that they enter the urethra obliquely in such a manner that there is a laplet of tissue covering each orifice so that it acts as a valve.

The utriculus prostaticus has a wide-open mouth which is unprotected in any way. Its walls contain a very great many tubules with branches that are fairly numerous and seem to contain all the elements which would tend to harbor infection for a long time. The utricle varies in size in all ages but seems to undergo a gradual increase in size up to the third decade. It is usually contained within the summit of the verumontanum but may extend to the base of the prostate.

The apex group of tubules which is first observed in a specimen seven and one-half months intrauterine is found in every older specimen examined. The number of these tubules varies from 9 to 26, with an average of 15. They occur at the apex of the gland, are frail in architecture, but extend fairly deeply into the coats of the urethra. They have many branches, and are lined with a mucosa composed of columnar cells.

THE WYOMING, SEVENTH AVE. AND FIFTY-FIFTH ST.

Impromptu Diagnosis of Atropine Poisoning.—Hunziker states that the picture of atropine poisoning is as a rule quite characteristic, but it happens occasionally that because of the attendant delirium a subject is rushed to an asylum. In any suspected case it is best to use the cat's eye as a diagnostic resource. If any suspicious drink or medicine is in evidence a drop of this is instilled into the eye, and this failing, a drop of the patients urine may serve the same purpose.—*Correspondenz-Blatt für Schweizer Aerzte.*

FROZEN LIMBS AND THEIR TREATMENT IN THE PRESENT WAR.

BY E. KILBOURNE TULLIDGE, M.D.,

PHILADELPHIA, PA.

FORMERLY CAPTAIN SURGEON IN THE AUSTRIAN ARMY; AND MILITARY SURGEON, FRENCH RED CROSS.

COLD is probably the greatest hardship and most dreaded enemy the soldiers of both armies on the Eastern War Front experience. For the cold there is no remedy; they must grin and bear it day after day. We have ridden on horseback through the blinding snow and sleet that froze to the horse's mane and tail, standing each hair out like the quills of a porcupine; slept in fur bags night after night on the cold, bleak snow of the mountainside, and trudged along the drifted roads when it was too cold to snow, until the first burning sensation of frostbite was replaced by numbness and complete loss of feeling in the limbs, from which the men dropped and were forgotten by the wayside, to revel in that overwhelming grip of tired, sleepy sluggishness that has for hours knawed its way to the end from which there is no awakening, a peaceful death.

We were riding with reinforcements to join that one man-of-the hour in all Germany, Von Hindenberg; it had been snowing for the past week, and our way led through the wooded Carpathians, already deep in snow. One evening I was aroused by a voice at my elbow, and, drawing rein, I learned after much difficulty, because of the wind and driving snow, that I was lost and alone with a medical student attached to my staff, and that we had been traveling aimlessly for hours on a densly wooded slope. We took a course due north by our compasses, and hurrying on came upon what appeared to be a tiny light some distance ahead. Following this beacon we soon emerged into a clearing, where to our delight we could distinguish what seemed to be several men sitting about the dying embers of a fire. I called to them, but received no response, and throwing the bridle of the horse to the student alighted and approached the circle. Not a soul stirred, and as I came closer I put out my hand and touched the nearest one of them on the arm. To my horror, he was stiff! Cold! Frozen to death, all six of them—four Austrians and two Russians—while they slept about the fire. They were bitter foes, united against a common enemy—cold, fatigue, and hunger; they had lost, and were there rocking in the wind to tell the tale to others.

Frozen extremities, particularly the feet, are by far the most common, and represent during the fall, winter, and early spring months the majority of all cases sent to the hospital, or treated at the front. The frequency and common suffering of this condition may be ascribed not only to the biting, intense, continual cold of the mountainous districts, but to a tendency due to the retention of the moisture of the feet, and to the inadequate blood supply of these points. The arteries should and must be kept warm where they are most exposed, and an endeavor made to prevent the occurrence of trophic and circulatory disturbances that lead to the more serious complications of gangrene, general sepsis, and death. With this end in view, proper and adequate clothing, socks, gloves, and wrist and ankle warmers of wool and cotton should be supplied to the troops in quantities large enough to allow of a change at least three times a week when on active duty, long campaign marches, and prolonged trench, marsh, and snow maneuvers. Warm, fresh, dry

socks and underclothes produce an effect both physical and mental upon the soldiers of a refreshing ease, soothing to the tired, sore, swollen, cold, moist feet and limbs. This necessity has been recognized by the German medical and military authorities, who have sent out, as the result of appeals and private donations to the men on the front, over 15,000,000 marks worth of half-cotton, half-woolen underclothes; 8,000,000 marks worth of cotton and woolen socks and ankle warmers; and the special "Military Committee for Warm Underclothing," formed at the suggestion of the Empress, woolen goods to the value of 20,000,000 marks.

Among the foot protectors sent by this committee were assorted sizes of yellow oiled and waxed paper covers shaped to go on the foot inside the boot. Some men display a predisposition to frostbite by pathological cardiac conditions and sluggish circulation in general. This should be recognized by the recruiting examiner or the regiment physician, and a note made that they should not be sent to exposed parts, although in the Carpathian mountain campaign all parts were more or less exposed, and the proper necessary care could not be taken along this line. However, the right man in the right place is a great medico-military secret of success toward providing for and sustaining the health and vigor of the troops. It must be remembered that probably the greatest factor of sluggish circulation and a most frequent and important one is fatigue. It is more pronounced, and occurs more easily in cold climates and high altitudes. Relief and frequent changes of the men upon active duty are necessary, and large, commodious boots, with no buttons or laces, should be supplied to them. Unfortunately, boots and shoes were at a premium on many occasions, and we were forced to devise large easy-fitting, straw-woven covers with a one to two-inch sole that could be slipped on over the shoes. These were of such excellent protection, keeping the feet warm and dry, that later many thousands were made and sent out by the government and Red Cross.

If early measures are taken to tone up the vessel walls and nerve supply of the legs and feet, frostbite may be avoided in the majority of cases. This can be done by daily cold baths, and massage with snow. Several officers with poor circulations treated in this manner benefited immensely. They stripped in the open every evening (behind a "lean-to") and received a complete massage of the entire body; first with snow and later with olive oil. They became so fond of the practice that it was continued during the whole winter campaign, with a resulting gain in weight and a marked improvement in their muscle tone.

The conditions manifest by the effect of cold upon the feet may progress from simple vasomotor disturbances and minute blisters, to total gangrene of the toes or even of the entire foot and leg. Soldiers standing for hours with their legs immersed in snow or cold water, which many times formed a crust of ice upon its surface, suffered mostly from a vasomotor condition, which, if left untreated, resulted in the death of the tissues and gangrene. A great factor in these cases is the persistent wearing by the troops of tight ankle-bands, boots, and puttees; swollen, water-soaked wool and cotton stockings and socks that constrict the leg and interfere with the circulation. The feet are swollen, inflamed, red, and blistered, paresthesia and anesthesia being at times present. The legs become edematous above the water-line, and the skin may break, displaying an open serous discharging wound. Some French authors term this affliction "water-bite," but I fail to disclaim its relationship as a first or primary stage of frostbite, held in check temporarily by the excessive moisture. We know that, if these cases are taken out of the water and placed in a dry, warm room the prognosis is better, and that, if they are allowed to remain outside, the dampness aggravates the condition, producing a maceration of the tissues and causing the shoes and other coverings to shrink still more.

The typical frostbite symptoms do not display themselves until on or after the fourth day of water or snow sojourn, but circulatory disturbances, if complained of during this time, should indicate an interference of some character, and all constricting bands about the thigh, knee, calf, and ankle should be removed, and massage of the entire limb ordered with the oil preferred by the soldier himself. Some authors, I have noticed, suggest the application, at this stage of a solution containing collodium, alcohol, glycerin, and iodine, both to the feet direct and to the sock; but I failed to obtain more benefit from the use of any or all of these preparations alone or in combination than that which results from applications of crude oils to the parts.

The circulation of both the blood and lymph is most sluggish toward the ends of the limbs, and because of this, artificial aid is required to treat the presence of extravasated blood in these regions; passive and active movements routinely practised should be recommended to the men while on duty, and prescribed even in the hospitals for bedridden cases of this nature. I know of one surgeon who, after elevating the affected limb, insisted that each morning after massage with alcohol and olive oil was given the patient lift his own extremity from off the inclined plane, and flex and extend the knee six times the first day, increasing daily until twenty movements were made, and then decreasing it. He claims that after one or two days the circulation improved, pain was relieved, and the tissues regenerated, recovering their normal character without gangrenous formations. This method I have not tried, but am inclined to favor a seven or ten day immobility with a daily massage, external friction, deep-breathing exercises, and hydrotherapy before motion is insisted upon. Hot coffee or caffeine is an excellent remedy in treating these early cases, helping to tone up the motor system with more favorable results than any other drugs tried.

In the later stages of frostbite there is a necrosis of the parts involved, usually the ends of the fingers, hands, feet, or toes. It may be classed as a dry gangrene, mummification, or death followed by inspissation if the tissues are bloodless at the time of freezing. However, most of these cases, in fact, practically all of 2,000 that I saw and treated, underwent a mortification or moist gangrene followed by putrefaction necrosis, accompanied by a great septic reaction and often death if the diseased area was not removed in time. Infection takes place very quickly from the slightest break of the skin in the early stages above described and spreads rapidly, accompanied by dysuria, oliguria, hematuria, disturbances in sensation of various parts of the body, and disorders in metabolism. The best treatment in this stage of the affection is at first friction with snow or cold water out in the open, where the patient should be kept for the first twenty-four hours, the change to a warmer atmosphere being gradually brought about. Friction or massage with oil or

alcohol—some prefer turpentine, benzine, alum, etc. —should be followed by elevation of the limb upon soft pillows after being wrapped loosely in cotton-wool over which is spread boric vaseline. These coverings can be held in position by bandages applied loosely so as to avoid any danger of constriction. Blisters and discoloration of the toes or other parts show that gangrene is imminent. At this period is the time to apply iodine tincture over the whole surface of the limb extending it far above and if possible below the involved area. The blisters contain a dark blood-colored serous fluid, and should be opened, carefully dried, and dressed with dusting powder, preferably powdered borax, salicylic acid, or zinc oxide. Every effort should be made to keep the parts dry and sterile when gangrene sets in. Incisions at or near the beginning of the inflammatory area may be made to allow the escape of accumulated and retained lymph and blood. They should be small, sometimes mere punctures, and extend through to the bone. If this is practised, a stimulating effect upon the capillary circulation and tissue regeneration will be noticed with the resulting diminution and decrease in the gangrenous involvement, thus saving as much of the injured extremity as possible. Immediate, early or too hasty amputation is absolutely contraindicated, as it is impossible to say how much of the damaged tissues will survive. It is true that a line of demarcation does occur, but the tissues adjoining it become more and more healthy, forming granulations significant of regeneration.

It is astonishing how an apparently serious gangrenous area or spot may contract and slough off, leaving a healthy but infected granulating area. Toes, and even completely involved feet, may regain their color and former healthy appearance in time if properly treated. Operation should, therefore, be delayed until at least it is evident that flaps of skin are available and can be applied conveniently so that they will make a good covering for the stump. The delay, however, should by no means await the spontaneous sloughing of the dead parts, because of the septic systemic infection that invariably accompanies it. Much to my sorrow, I followed the advice of others, among whom were Profs. Walther, P. Thiery, and Goutley, in the early days of my service, and waited until cicatrization had accomplished as much repair as it could, allowing spontaneous sloughing, with the result that death carried with it five of the boys who would probably have been saved by earlier operation at the proper time. To operate upon these cases, the surgeon must know thoroughly the operations relative to amputations and disarticulations of and about the feet and hands, especially the former. Of these, Lisfranc's, Chopart's, Syme's, and Pirogoff's operations are of most value and of great importance in that a fairly presentable limb must result that will be of some use and service in after years.

The first of these operations, Lisfranc's, is best performed by making a short dorsal and a long plantar flap, and disarticulating the toes and anterior portion of the foot at the tarsometatarsal junction or line, the stump being composed of plantar and dorsal tissues. The incision begins behind the base of the fifth metatarsal bone, passes straight down the outer side of the foot about one inch, then around onto the dorsum and crosses the foot with a slight downward convexity, parallel with, and just below the tarsometatarsal joints, reaching the inner border of the foot about one-half inch below the tarsometatarsal articulations. From there it rounds into the inner aspect of the foot and passes straight upward, ending above the cuneiform-metatarsal articulation of the great toe. This completes the dorsal flap.

The plantar flap incision with the horizontal portion of the dorsal incision passes down the outer lateral side of the foot, along the plantar edge of the fifth metatarsal to below its middle, then gradually rounds onto the sole and sweeps obliquely across the plantar surface, crossing the fifth metatarsal just above its neck, and ending at the first metatarsal-phalangeal joint. This incision is joined to the dorsal incision by an incision running up the mid-lateral aspect of the foot, along the border of the first metatarsal. Care should be taken not to make the dorsal flap too short or either flap too pointed, allowing plenty of soft tissue on the plantar flap to compensate for postoperative sloughing, and not to mistake the scaphocuneiform joint for the metatarsocuneiform articulation.

The incision above described should be deepened and carried down to the bone at the line of demarcation, or just above, allowing enough room for clean fresh flaps. The vessels are often already closed by thrombus formations and rarely need ligation. The flaps must be left open and not closed by sutures, allowing the parts to drain. Wet sublimate dressings, if warm and applied twice daily for the first four days, will soon control the septic serous discharges, and stimulate healthy granulations in the course of two weeks.

Disarticulation of the foot at the mediotarsal joint may be done by a slight modification of Chopart's flaps: "a short dorsal and long plantar," and substituting a modified oval flap as described by Tripier, with the horizontal sawing of the os-calcis. Chopart's, however, I found to be much simpler and by far the quickest and best operation. It consists of the disarticulation of the anterior portion of the foot at the astragaloscaphoid and calcaneocuboid joints, being somewhat similar to Lisfranc's operation.

The plantar incision begins on the outer aspect of the foot at a point opposite the calcaneocuboid joint, and passes down the outer side of the foot to the middle of the fifth metatarsal, then around to the sole of the foot along the middle of the metatarsal to the inner side of the foot, passing straight up that border to a point opposite the astragaloscaphoid joint. The dorsal incision begins by curving from the outer limb of the plantar incision, just posterior to the fifth tarsometatarsal joint, and ends by curving to meet the plantar incision of the opposite side at its tarsometatarsal joint, crossing the foot at the dorsal level of the bases of the metatarsal bones.

The incision should be deepened down to the bone, and the disarticulation performed from the dorsal surface, while the foot is forcibly extended by an assistant or by the operator's left hand. The tendons of the tibialis anticus and posticus, peroneus tertius brevis, and longus are cut and the extensor tendons and tibialis anticus of the dorsal flap sutured to the plantar flap. This will help to counteract the tendency that exists for the displacement of the bones of the stump by contraction of the tendo-Achillis, which throws in many cases the head of the os calcis downward, causing pain from pressure on walking.

Pirogoff's operation is also necessary to resort to when the heel of the foot has become frozen and sloughs off with the toes. The intervening tissue on the arch of the plantar surface of the foot that re-

mains in a living condition is often so small or so inflamed that it is not worth while saving, and the disarticulation of the foot at the ankle joint with the removal of the malleoli, the articular surface of the tibia, and the anterior part of the os calcis is necessary. A modified dorsal flap is necessary, as a heel flap is impossible. This if tried will give good results, although a fleshy person will produce a better flap than a lean one. Sometimes the foot is frozen so badly and the area of necrosis so extensive that it becomes necessary to perform Syme's operation, which is indeed a far better operation for both the patient and the surgeon if performed with a dorsal flap. This is a disarticulation of the foot at the ankle joint with the removal of the malleoli, the articular surface of the tibia and fibula being sawed transversely at about one-quarter inch above the inferior border of the tibia. The anterior tibial, external malleolar of the posterior tibial, and internal plantar, anterior peroneal, internal malleolar of the posterior tibial and internal and external saphenous vessels are ligated; the nerves are all cut short, especially those of the heel-flap bent over the ends of the sawed bones, and the wound remains open and is dressed as above with a wet bichloride dressing for the first four or five days.

Watson of the British Army has devised a method of amputation at the ankle joint when necessary that leaves the heel intact, and in his opinion provides a more serviceable stump than obtained from Syme's or Pirogoff's amputations. He amputates the foot in front of the os calcis, removes the lower ends of the tibia and fibula, and the upper surface of the os calcis, wedging the os calcis up between the malleoli, pinning it there with a pin that may be removed in about two weeks, thus leaving the walking surface of the heel intact, preserving the malleoli to give a firm hold to the "uppers" of the shoe and permitting the patient to wear an ordinary padded shoe.

If the toes or fingers alone are involved, disarticulation at the first joint behind the line of demarcation should be performed, permitting ample space for free tissue drainage of the open infected stump, and sufficient tissue to form a respectable flap when the infection has subsided. Amputations of all the toes or fingers through the metatarsals were frequently easily and simply performed, giving good results. Care in these operations should be taken to replace the tendons of the flexor and extensor muscles suturing them into the mouth of the cut theca and periosteum or even the flap, and thereby secure control of the stump. The operation is a simple one, the palmar incision beginning opposite the saw-line on one side and carried down in a circular curve one and one-half times the diameter of the finger, to end on the opposite side at the same line as the starting point. It is deepened to the bone, and the bone should be disarticulated; the digital artery may or may not be ligated, as the case demands. The deep flexor will, however, be severed and should be sutured into the mouth of the fibrous sheath ending at the middle of the second phalanx and into the neighboring periosteum and soft parts if necessary. The flap is then allowed to remain open and a wet sublimate dressing applied to facilitate drainage.

Other amputations and disarticulations are so simple and so commonly and thoroughly discussed by other authors that I will not mention them here.

Care and attention are required in the after-treatment of these finger and toe amputations and disarticulations. Exercises, passive and active, should be commenced at the end of the first week to keep up the strength of the muscles, particularly the extensors, for they degenerate faster than the flexors. The remaining fingers or parts of fingers and toes should be left exposed or in a condition of easy mobility so that the patient can keep them continuously working vigorously to ward off stiffness. Enough of the hand should be left if possible to permit the patient to grasp things with, as there is no feeling and little comfort in an artificial hand, which is decidedly inferior to a mutilated stump that still has grasping and holding powers. Lastly, when placing the arm in a sling, care should be taken that the hand does or will not drop from its own weight or receive pressure from the edge of the supporting binder.

THE PRESENT CONCEPTION OF CONGENITAL SYPHILIS AND ITS MODERN DIAGNOSIS.*

By ADOLPH ROSTENBERG, M.D.,

NEW YORK.

ATTENDING DERMATOLOGIST TO THE GERMAN HOSPITAL O. P. D. AND TO BRONX HOSPITAL AND DISPENSARY

THE epoch-making discoveries of the last decade in syphilography have along with other changes also necessitated an important revision in our conception of congenital syphilis. Up to ten years ago it was more or less the general belief that germinative transmission was the common mode of infection from parent to child, that is a transmission through either spermatozoon or ovum or both. The strongest support for this theory was given through Colles' law, whereby a syphilitic child could be the offspring of an apparently healthy mother, even transmitting an immunity to the mother against a syphilitic infection in later life.

Matzenauer in 1903 in his Monograph, "Vererbung der Syphilis," guided solely by clinical and pathological observations, doubted the correctness of this theory and maintained that it was the mother alone, carrying the infective agent in her placenta, who transmitted the disease to her offspring.

With the discovery of the Wassermann test and the finding of the sphirochetes it could be shown that Matzenauer was correct with his placental theory, as in every specific case spirochetes were found by all investigators in the intervillous spaces and the maternal portion of the placenta; besides the Wassermann was found strongly positive in almost 100 per cent. of all these cases even when the mother clinically did not show any specific manifestations.

And must we not admit from theoretical deductions alone, how improbable the germinative transmission of congenital syphilis appears? Does it not seem rather impossible that the spermatozoon or ovum could develop, if invaded by a host of living parasites? Now that we understand Colles' law correctly, we are able to explain why syphilitic children with frank lesions on mouth and lips, could nurse their mothers and would not infect them, whereas the same children would invariably infect a wet nurse. These so-called Colles mothers unfortunately were infected with lues long before their offspring was born, the disease was only latent in their system, and therefore we find this apparent immunity against a specific infection in later life.

*Read at a meeting of the Bronx County Medical Society, March 15, 1916.

In view of these facts it seems for all practical purposes justifiable to assume, and most authors take this stand to-day, that there is no congenital without maternal lues. If so, the placenta must be the high road through which the infection goes. From the placental blood vessels the spirochetes are carried to all the fetal organs. This fact explains at once the principal difference in the dissemination of the virus in acquired and congenital lues. In the latter we have no primary lesion as the starting point, from which the infection travels, first through the lymphatics and thence in the blood stream. In congenital syphilis, as just said, the spirochetes are carried from the mother's placenta into the fetal blood vessels, thus establishing a condition which practically corresponds to the early secondary stage of acquired lues. This fact also explains why congenital syphilis acts so deleteriously on the fetus in a recent infection. Here the spirochetes, which are found in greatest abundance in all the internal fetal organs, will naturally produce a severe septicemia through their toxins, and to this the majority of these unfortunate beings succumb, before they have reached their full development. According to Kassowitz, only three-fifths of all luetic offsprings go to full term, and other statistics show even a higher mortality in this respect.

After these theoretical considerations let us outline more in detail the various modes and possibilities through which the fetus acquires its congenital infection.

I want to state right here that the mother may sometimes infect her offspring without showing manifest clinical symptoms herself. This is also a cardinal differential point between congenital and acquired lues, as in the latter lesions on skin and mucous membranes only transmit the infection to another individual. Whether the fetus will become infected at all depends on a variety of circumstances, which are sometimes very complex and often very difficult to understand.

Let us assume at the beginning that both parents are suffering from a manifest case of lues at the time of conception. In such a case the fetus will hardly ever escape; a severe spirochetal septicemia will cause an abortion or an early miscarriage, the macerated fetus showing all the stigmata of congenital lues. In a few instances, especially when some form of treatment has been instituted during pregnancy, a living child may be born, but soon some grave specific symptoms will develop, causing an early death of this unfortunate being in most cases.

If the mother alone was syphilitic at the time of conception, the offispring will be in the same danger as before, especially if the mother had none or insufficient treatment and married during the first two years after her infection. If the mother was free from syphilis at the time she conceived, but contracted the disease while already pregnant, then the fate of the child will greatly depend upon the period of gestation at which the infection took place. Here different observers have come to contradictory conclusions. Some claim that the infection is transmissible to the offspring only during the early period of gestation, whereas others maintain that the infectiousness is more intense during the second period and increases as the pregnancy approaches full term. Does the child ever escape infection at all? According to the so-called law of Profeta it does. Unfortunately though, Profeta's law has also been proven to be untenable in the light of our recent investigations. The apparently healthy children, born of mothers who became infected *post conception*, remaining, according to Profeta, free and even immune against a syphilitic infection in later life; these children give, according to most investigators, a positive Wassermann reaction, which shows that they do suffer from a latent form of lues and acquired their infection during intrauterine life.

A paternal infection is ordinarily not so serious to the offspring as a maternal one. If we adhere to Matzenauer's placental theory, the paternal infection is of no consequence at all unless the mother becomes infected also. This positive statement of Matzenauer seems, however, to have been somewhat shaken recently since Finger and Landsteiner have succeeded in inoculating monkeys with the spermatic fluid of a syphilitic man and obtained luetic manifestations, thus proving the contagiousness of syphilitic sperma, in spite of the absence of spirochetes in the spermatozoon. Bab has also found a positive Wassermann reaction in the sperma obtained from syphilitics. These findings may now explain a few rather strange cases which were called by Fournier infection through *choc en retour*, whereby we find the following: A healthy mother conceives from a syphilitic father, who does not show any infectious lesions anywhere on his body at that time. But the mother without having had a primary lesion, develops early secondary symptoms in the first half of her gestation; an abortion usually follows and the fetus shows all the earmarks of congenital lues. In these cases, according to Fournier, the fetus received the syphilitic virus from the father's sperma and infected its mother through the placenta. These cases, however, are so extremely rare, that to my mind they should not offset the placental theory of Matzenauer and for all practical purposes we ought to adhere to it as the only plausible mode of congenital transmission of syphilis.

That early and rational treatment will ameliorate the symptoms and modify the issue in congenital syphilis is self-evident. But even untreated cases show, according to Kassowitz, a tendency toward a gradual diminution in severity, ameliorating with the duration of the disease in the parents. Therefore we find as a rule in syphilitic families first abortions, then stillbirths, then living premature infants, then living syphilitic infants, born at full term, but showing syphilitic lesions, then living full term children, free from specific lesions or showing them only after birth, and finally entirely healthy children at birth and remaining so afterwards. Of course this is not an ironclad rule and exceptions are seen frequently, so that sometimes healthy and syphilitic children alternate in successive pregnancies.

It is generally accepted and obviously seen from the closer contact of mother and child, that a maternal syphilis will persist in its infectivity much longer than a paternal one; therefore we see cases in which a syphilitic woman, joined in second marriage to a perfectly healthy man, bears him syphilitic children; such transmissions have been observed as late as twenty years after the mother was infected.

As to the diagnosis of congenital lues, I do not know of any other instance where the physician's responsibility is taxed to a greater extent than here. It is not only the case in question, but the

outcome for the future, which depends on the correct diagnosis thus leading to the correct treatment and so offering much brighter prospects later on.

It goes without saying, that in all cases of pregnancy, where manifest luetic symptoms are noticed in either or both parents or where the Wassermann test taken as a precautionary measure, without the presence of lesions, reveals a positive reaction, a very prompt and intensive specific treatment should be instituted at once. Unfortunately though such cases are in the very small minority, the family physician as a rule gets his first inkling of suspicion when he is called to attend a case of an abortion or an early miscarriage, and I want to state right here that we should suspect lues in every case of spontaneous abortion or miscarriage, occurring in an apparently otherwise healthy woman. Statistics from various large obstetrical institutions will bear out this statement. So found Ruge in Breslau, in a series of 94 abortions in 78 cases lues as the only causative factor. Professor Williams of Baltimore has shown on a material of 1,000 consecutive pregnancies, in which 705 resulted in still-births, that 26 per cent. of these were due to syphilis.

What are the characteristic diagnostic features in a stillborn syphilitic child? As a rule the skin will be found macerated and peeling off; this phenomenon, however, may occur in any fetus which has died from any cause and has been retained *in utero* for several days or longer, before being expelled. Tissier, however, found, on examining 155 macerated fetuses, in 99 the presence of syphilis, and 95 per cent. of all macerated fetuses were found to be syphilitic by Boissard. We therefore are justified in suspecting very strongly the presence of syphilis just from this condition alone. But all the internal organs will furnish more abundant evidence. The thymus gland is enlarged and contains multiple abscesses, the lungs show the so-called white hepatization, the liver, spleen, pancreas, kidneys, adrenals are all greatly enlarged due to an interstitial fibrosis and gumma formation. In all these organs spirochetes are found in abundance. At the ends of the long bones there is a broad zone of ossification between the diaphysis and the epiphysis with very irregular proliferations; in the bone tissues are found islets of cartilage and in the cartilage islets of bone tissue, a process known as "Wegner's osteochondritis." The placenta is also of great diagnostic value in these cases. Its size and weight are larger than normal and its consistency is more solid. On cutting, the tissue appears more friable and looks like sausage meat; the weight, instead of being about one-sixth of that of the fetus, may be one-quarter or more and this latter phenomenon alone, if not due to edema or the presence of cysts or tumors, should be looked upon in itself as strongly suggestive of syphilis. Microscopically we find the presence of gummata, vascular changes in the stroma of the villi, decrease in the number of the blood-vessels, partly due to a periarteritis and partly to an increase of stroma-cells of the villi. In the decidual portion we find a gummatous endometritis. The umbilical cord is thick and there is a marked hypertrophy of the connective tissues and thickening of the walls in the umbilical veins. Spirochetes are also found in all these different structures. It rarely happens that syphilitic infants are born alive, showing specific symptoms at birth; if they are, however, the children look puny, ill-nourished, have a shriveled appearance, blue extremities and a hoarse, feeble cry. The majority of congenital syphilitic children surviving their intrauterine infection are born with a clear skin and apparently in perfect health, but soon our suspicion will be aroused, for characteristic symptoms develop as a rule between the first and twelfth week of life. Desquamating patches on the palms and soles may be seen during very early infancy and occasionally syphilitic pemphigus may come on within a day or two after birth; if the eruption is severe, the child usually dies. The changes that take place within the first few weeks in an infant, who appeared healthy at birth, are such that it gradually seems to waste away. The skin, which is wrinkled, assumes a dull earthy color and there is evidence of marked anemia. The face assumes a careworn expression, and looks like that of a little old man. Various external lesions make their appearance, such as pemphigus, rhagades at the mouth, which may be so painful as to interfere with nursing, condylomata around the anus, and a copper-colored rash on buttocks and back. Snuffles is a very characteristic symptom. At this time various internal changes also take place, affecting important visceral organs and undermining the little patient's general health to such an extent that death soon relieves all its sufferings, especially if no proper and energetic treatment has been instituted. All these clinical symptoms are characteristic enough to enable us to make a correct diagnosis. But if still in doubt, the Wassermann test will be of additional value, for, as we have seen above, nearly 100 per cent. of all mothers giving birth to syphilitic children show a positive reaction. Therefore, it will be our duty to examine the mother's blood in such a case. The Wassermann test in the infant is unfortunately not reliable enough, as we frequently get a negative reaction in spite of positive lues. This phenomenon has been explained by the fact that a certain amount of immunizing substances have been transferred from mother to child, sufficient to counterbalance the development of a number of spirochetes, thus weakening the formation of antibodies and therefore leading to a negative Wassermann. As soon as manifest lesions develop, and in later life of the infant, the reaction will become positive and follow the same rules as in acquired lues.

In conclusion I want to make a final appeal to the family physician, as he is the first one, as a rule, who is called upon to make the diagnosis, to recognize congenital syphilis or at least to suspect it in a given case, and then to demand a Wassermann test of the mother. Only then can such an appalling waste of human life, as due to congenital syphilis, be reduced. According to the best statistics 50 per cent. of all syphilitic children are born dead and of those born alive 75 per cent. die within the first year, most of them during the first few weeks of life. The survivors, as a rule, go through life physically and mentally damaged, a living reproach to the misfortune of their parents.

1872 Washington Avenue.

Granuloma Pyogenicum.—C. D. Wescott reports a case of granuloma pyogenicum occurring in a boy aged 9, and affecting the eye. It was located just above the edge of the left upper lid and caused serious anxiety for fear of cancer, the disease of which the child's father had died. Wescott says the two conditions simulating this growth are cancer and chancre. Although persistent and liable to recurrence, it is usually treated without much difficulty. The tumor in this patient was removed and the wound cauterized; it healed, leaving a very small scar.—*Journal of the American Medical Association.*

THE IMPORTANCE OF BLOOD PRESSURE TO THE EYE SPECIALIST.

By F. P. HOOVER, M.D.,
JACKSONVILLE, FLORIDA.

THE taking of the blood pressure in many instances has to me been most satisfactory; it has given me a clearer and better understanding regarding such cases as incipient Bright's disease, for instance, after examination with the opthalmoscope. I always prefer to take the blood pressure myself in my office than to have it taken by someone else, no matter what report may have been rendered me by the attending physician (if one were in attendance prior to my seeing the case). I have come to look upon my instrument as a necessary adjunct to my office equipment. Time in taking these readings should not be considered. As, however, the specialist rarely goes beyond his domain, the taking of blood pressures by many is not considered to come within their jurisdiction; it does not belong in their line of work; it is an incroachment upon the work of another. My ideas are at variance with those who feel that taking a blood pressure should be left to another entirely, but this is merely a matter of opinion and preference. I have always felt when a man went to a specialist on the eye, not to a "doctor of optics or optometry," he does so because he desires positive information regarding his condition. He may never have had medical attention before in his life, or since childhood, and it is fair to that man, should the trouble be retinitis albuminurica, for example, to turn him loose with orders to consult a general practitioner before seeing you again, until you have personally investigated his condition more fully, if for no other reason than that of impressing, by a thorough knowledge of the case, the great importance of prompt medical attention, for there are men and women who, unless you force, so to speak, a realization of what is the matter with them, will in all likelihood leave your office and never see a doctor until they are beyond help. I have noticed this more especially in the less well to do, those who in the majority of instances have strained a point to see a specialist and cannot afford additional expense; yet these same people more often follow instructions implicitly than those who are better off and have more of this world's goods.

In taking the blood pressure the auscultatory method is by far the easier and more satisfactory. I used to take it by palpation, but the former method is much more reliable. The systolic pressure alone gives too uncertain a reading to warrant a diagnosis, for it is more easily influenced by general conditions. In more than 90 per cent. of my cases the pulse pressure averaged from 30 to 35; my cases ranged from sixteen to seventy years of age. Sometimes the pressure was abnormally high in patients who were in first-class condition; for instance, a man thirty years old came to me with a foreign body in his eye; after its removal and seeing my sphygmomanometer, he asked what it was for and, when told, said he wished his blood pressure taken. This proved to be: systolic, 130; diastolic, 100; pulse, 50, the record being taken three times. A few days later he called again, and I took the blood pressure once more; it was exactly what it was at the previous visit, and yet this man had no organic or physical ailment, spent a great deal of time out of doors, was not of a nervous temperament, had no business or domestic worries, and was a splendid specimen of manhood 5 feet 11 inches tall and weighed 195 pounds. Nicholson says "the diastolic pressure is between 60-105 mm. Hg.; a diastolic pressure above 105 mm. Hg. would be a sure indication of hypertension, regardless of the age of the patient."

In the aged, high blood pressure need not necessarily prevail, neither should a snap diagnosis be made in the event of a high blood pressure without due consideration. There are many elderly people who have had a high blood pressure for a long time; they should be kept under observation, for a sudden lowering of the blood pressure might be disastrous for them, owing to its effect upon the heart.

I have found the blood pressures to vary somewhat in diseases of the eye: in hemorrhage of the eye, high; in recurrent conjunctivitis with a rheumatic history, usually high; in retinitis albuminurica, high; in hysterical blindness, high; traumatism of the eye, in the majority of instances, high, but we do not always see these cases until some time after injury; in orbital cellulitis, high; in exopthalmus, in the only case of the kind I ever took a blood pressure, high; in optic neuritis, high; in the nervous affections, varied; in keratitis, retinitis, and various inflammatory conditions, varied, except where there has been great pain, etc., as in iritis, and where there has been very little rest or sleep, the pressure has been high, in chronic eyestrain with more or less constant headache, pain in or over the eye, pain in temples or on top of the head, inflammation of the lids, the pressure is high. We find this condition especially in bookkeepers and those who use their eyes constantly for near work, electricians, draughtsmen, painters on china or those who work much on dark goods or glazed material, those who sew for a living, proofreaders, typesetters, cooks, etc. I do not mean to say the eye may have been responsible for the high blood pressure, for some condition in the heart, kidneys, or nervous system in all probability was the direct cause, but, nevertheless, in the various affections of the eye named, I have found a blood pressure not normal. I have said nothing regarding syphilis or alcohol as a cause of eye trouble; in the event of either a high blood pressure is expected. I do not wish to be misunderstood in this article to state the absolute necessity of taking a blood pressure in all of our eye cases, but I do say by so doing, many times, one can locate some underlying cause that plays an important part in the disease we have under our care. In throat work in several instances I have taken the blood pressure, and also in my ear cases; in the former in acute bronchitis, tonsilitis, laryngitis, asthma, also when inflammation was accompanied by neuralgia or rheumatism or gout, the pressure was varied, more often high. In sufferers from anemic or run-down conditions, in cases bordering on break down, and in diabetes, the blood pressure was usually low. In acute otitis, in furunculosis, in acute mastoiditis, in bulging of the drum membrane, prior to rupture, and in cellulitis, I have found the blood pressure high.

MUTUAL LIFE BUILDING.

Indications for the Use of Ergot.—Sinha says that, as ergot contracts unstriped muscular tissues in all parts of the body and its action is not confined solely to the organs of reproduction, it should be given when the skin is pale, cool, and relaxed, bathed in cold, clammy perspiration, the mucous secretions being increased, with or without involuntary passages from bowels and bladder.—*Indian Medical Record.*

SOME DEFORMITIES OF THE HEAD MENTIONED IN THE TALMUD.

AN HISTORICAL NOTE.

By DAVID I. MACHT, A.B., LL.B., M.D.,

BALTIMORE, MD.

AMONG the most interesting malformations of the head met with by the modern clinician are those due to rickets, acromegaly, and osteitis deformans. The history of these conditions is interesting and is of a comparatively recent date. Osteitis deformans was first described by Sir James Paget in 1877 and is sometimes known as Paget's disease.[1] Acromegaly, the interesting condition which is now regarded as related to disease of the pituitary gland,[2] was first described by Marie,[3] in 1886. Even rickets, though probably a very old condition, was first described by Glisson[4] in the seventeenth century and is regarded as a disease of modern civilized life, distinctly occidental in origin. It is the morbus anglicus or English disease, and the term rickets is originally from the English *wrickken*, to twist. Rickets was a rare disease in the ancient Orient.

In the course of some researches into the history of medicine among the Semitic nations, I have come across some passages in the Babylonian Talmud which are of interest in connection with the above named diseases. It is a matter familiar to every student of the Bible that the Hebrew priests were required to be physically, as well as morally, perfect—without a bodily defect or blemish—in order to be eligible to service in the Temple.[5] The Talmud, in the tractate *Bechoroth*, enumerates several defects which disqualify a priest from ministering in his holy office. Among these, I was particularly struck by three—the *kilon*, the *lafton*, and the *maqbon*.

The condition of *kilon* is described as a person having a peculiarly shaped head which is pointed at the top, and broad at the bottom.

The *lafton* was a man with a head shaped exactly the opposite of the preceding. To use the expression of the Talmud he had a head, very broad at the top and narrow at the bottom, like a *lefes*, *i.e.* a pumpkin.

The expression *maqbon*, derived from the word hammer, refers to a hammer-shaped head, or as the Talmud describes it, one with a prominent and projecting forehead and occiput.

The terse descriptions of the kilon-head and lafton-head, given by the Talmud, could not be improved on by any modern text book in medicine. Take, for instance, the excellent treatise on diagnosis by Musser. We have there a description of the skull shapes in acromegaly and osteitis deformans, namely a triangle with its base below and apex above in the one case, and the reverse in the other, which matches exactly with the Talmudical description. The diagrams drawn by that author emphasize the similarity still more.

The Hebrew description of "hammer-head," as applied to the rachitic skull is also very characteristic. The classing of the rachitic deformity with the two others, tends further to confirm the rarity of rickets among the ancient Hebrews. That condition, thanks to their dietary and other hygienic laws, we know to have been a very rare one among them, and was therefore probably as unusual and striking as acromegaly or Paget's disease is among us. It is thought that the above references to skull deformities are of sufficient historical interest to be worth noting, especially as the original sources are not accessible to most medical men.

Medicolegal Notes.

Expert Evidence in Malpractice Cases.—In an action for damages against two surgeons for failure to exercise reasonable care and skill in treating a compound fracture of the bones of the plaintiff's right arm, the evidence only showed the acts of the defendants in getting the injured bones as observed by the plaintiff and his wife, the nature of the treatment by one of the defendants thereafter as they observed it, the statements of the defendants as to their belief that the arm would be restored to its usefuness, and the fact that the arm was not straight when the splints were removed. There was no evidence from any physician to give the jury a standard to determine the fact of reasonable care and skilfulness, and it was held that the question was therefore one of law for the court, as to permit the jury to determine it without such expert evidence would be to allow them to decide it from mere speculation and conjecture. Judgment for thedefendants was affirmed.—Adolay v. Miller, Indiana Supreme Court, 111 N. E. 313.

What Constitutes Practising Medicine. — On a trial for practising medicine without a license the defendant contended that the evidence was not sufficient to show that he was guilty of violating the Iowa Medical Act, or that he held himself out as a physician and surgeon, or publicly professed to cure and heal, or that he made a practice of healing and curing. The substance of the evidence was that one witness went to the defendant's house to ascertain if the defendant would treat him for rheumatism; he said he did not remember what the defendant told him, but he took four or five treatments, these being performed while the witness was lying on a sort of bench, and the defendant worked on his spine and legs. The witness did not have any arrangement as to charges, and never paid the defendant anything.

Another witness testified that the defendant came to his house and gave him a treatment. This was done by an adjustment of some of the joints of the witness's spine. He was stretched out on a bench which the defendant had brought with him. This witness took three or four treatments and gave the defendant $5.

Another witness said the defendant treated his wife for goiter by rubbing the goiter and the spine; the patient also had gas in the stomach, and the defendant rubbed the stomach. For this the defendant received $20 for 24 treatments.

Another witness testified that he had one of his arms out of place, that he had sought treatment without avail, and finally, meeting the defendant on the street, asked him to see if he could put his arm in place, which the defendant did.

The court thought the evidence was sufficient to take the case to the jury on the question as to whether the defendant assumed the duties of a physician, and that he publicly professed to cure and heal. The conviction was affirmed. State v. Booher, Iowa Supreme Court, 155 N. W. 167.

Prosecution for Practising Without a License.—The Missouri statute declares that any person practising medicine or surgery without a license from the State Board of Health, or after revocation of such license, shall be deemed guilty of a misdemeanor, provided that physicians registered on or prior to March 12, 1901, shall be regarded for every purpose as licentiates and registered physicians. An information charging the accused with practising medicine without a license did not negative the exception. It was held that as the exception was not contained in that portion of the statute defining the offence it was not necessary to negative it in the information, but to be available as a defence it must be insisted on by the accused.—State v. Saak (Mo.) 182 S. W. 1074.

MEDICAL WORK AND WAR.

THE threatened war with Mexico and the mobilization of the State militia have given an opportunity to the American Red Cross and to the medical units attached to the National Guard as well as to the Departments of Health to show in how far they have profited by the experiences of the past few years. The showing so far has been satisfactory. In New York, for example, the State Department of Health has on hand, as a consequence of having foreseen the possible demand, sufficient typhoid vaccine to immunize every member of the New York State National Guard against this disease, and is now sending it out to the mobilization camps as rapidly as it is needed. The excessive morbidity and mortality of the Spanish War will thus be avoided. The first field hospital, the original of its type in this country, and the Third Ambulance Corps, both from New York City, the latter under the command of Capt. L. H. Shearer, M.D., of Bellevue Hospital, and the former of Major J. Franklin Dunseith, M.D., of the City Department of Health, were among the first units to reach the concentration camp at Beekman, N. Y. The sanitary conditions at the mobilization camp are in charge of Col. William S. Terriberry, M.D., of New York, who will have each man inoculated against typhoid, and will forbid the eating of any food except that prepared in the camp kitchens.

Through timely gifts the New York branch of the American Red Cross has been enabled to complete its equipment of eight base hospitals of 500 beds each, the hospitals being manned by members of the staffs of the New York, Presbyterian, Mt. Sinai, Bellevue, Lincoln, German and the Post-Graduate hospitals. The eighth unit is the Naval Base Hospital in Brooklyn. Corresponding to these New York units a number of other units are being planned in other cities (thirteen in all are organized), which will give the Red Cross a total equipment for over 15,000 beds. The New York branch is also conducting classes in first aid and the care of the sick, in order to have volunteer helpers available, and these courses will be continued throughout the summer. Six thousand Red Cross nurses are holding themselves in readiness for mobilization orders, according to the statement of the executive secretary of the New York headquarters. The Preparedness League of American Dentists has opened a registration bureau in Buffalo in the hope of enrolling 20,000 dentists who will prepare free at least one applicant each to meet the requirements for enlistment in the Army, Navy, or Marine Corps. The standard of enlistment requires the applicant to have at least twenty sound teeth, with four opposed molars and four opposed incisors. Properly filled teeth are counted as sound.

TWO VIEWS OF TOURNIQUETS.

ALL the devices of surgery are being tried out on a gigantic scale in the European war, and the surgeons of America are awaiting the verdict of their European colleagues on many points, just as a half century ago the situation was reversed. Many a surgical procedure, beneficent in the hands of a surgeon in the operating room and admirable in theory, does not justify itself when put to the stern test of the battlefield. Among the doubtful instances the tourniquet may be mentioned. This appliance has a limited field of usefulness in the modern operating room and a wholly disproportionate value in the minds of the laity who recall newspaper accounts of persons saved from bleeding to death by the prompt application of a tourniquet improvised from a handkerchief by a quick-witted bystander. At any rate, the European soldier is furnished with a rubber one in his first-aid packet and instructed in its use, the theory being that unnecessary loss of blood can thus be prevented.

Professor Albrecht of the Austrian Army, quoted in the *Wiener medizinische Wochenschrift*, calls attention to cases of gangrene resulting from rubber tubing tied around a limb to prevent hemorrhage. These, he said, were usually due to the fact that after such a bandage had been placed, either the surgeon or the patient would be transferred elsewhere. He suggested that such cases should be plainly labelled "rubber tourniquet." Unfortunately in many cases only the outer dressings were changed and the pressure of the tourniquet was not discovered until gangrene had set in. Some cases were due to the application of the tourniquet by the soldier himself who was later unable to remove it or did not dare to do so.

On the other hand, Dr. R. P. Rowlands, surgeon to Guy's Hospital, writes in the *Lancet* for May 13 a plea for the more thorough use of the tourniquet in peace and war. He believes that many lives have been lost because sufficient pains were not taken to prevent the wounded from losing still more blood. This extreme loss of blood causes a secondary anemia which handicaps the patient and also increases the risk of sepsis and other complications. The rest of Dr. Rowland's letter is chiefly concerned with the technique of amputation, his only allusion to the use of the tourniquet in war being where he says, "during this war I have tentatively extended the method to the septic wounds now so common, and with very satisfactory results."

Professor Albrecht's comments on the tourniquet seem much more pertinent, dealing as they do with

his observation of cases on the battlefield where the after-care of the patient had not been properly carried out. The correct view would seem to be that the tourniquet has a proper and very useful place in battlefield surgery, but also that every case in which a tourniquet has been applied should be given very special attention and wherever possible should be attended by the same surgeon for at least forty-eight hours after the application of the bandage.

THE BLOOD IN EPILEPSY.

It is hardly necessary to recall to the minds of the profession the many theories that have been held in the past regarding the nature of epilepsy. The explanation of the ancient Romans who believed that epilepsy was a visitation of the gods and that of the present-day savages who think that ancestral spirits enter the body and fight the indwelling spirit, causing convulsions, seem to be as plausible as any. Accompanying the varying theories, inevitable sequellæ of them in fact, many kinds of treatment have had their day. Nearly every drug in the Pharmacopeia and every one reputed to be a sedative, has had its trial. The bromides, opium, chloral, cannabis indica, borax, solanum carolinense, adonis —the list could be extended almost indefinitely.

Lately more spectacular forms of therapy have had their vogue. The psychoanalysts, *e.g.* have maintained that in the epileptic convulsion we have a parallel to the incoordinate movements of the infant when he comes in conflict with his environment, that epilepsy in fact represents a regression of the individual to infantile levels. Their method of approach to the problem would be an analysis of the convulsion itself to see how it represented the conflict and then an endeavor to get the patient to adjust himself to his conflict in a way more compatible with social conventions. We all know something of the treatment with rattle-snake venom, or the crotalin treatment. Then we have tried recently a serum obtained from the blood of other epileptics.

With this latter method is associated the name of Spangler, who reports further studies of his on the blood in epilepsy in the *Lancet* for April 29. His observations were made on 369 private patients, not institutional cases. He finds that the hemoglobin is high in the disorder, averaging 84 per cent., in his series of cases. This is at variance with Fackenheim, who found an average of not quite 60 per cent. Of course Spangler's cases appear to be from a somewhat higher social plant and therefore present the factors of better nutrition, hygiene, etc. The latter observer found no marked diminution in the red blood cells and no degeneration of them; the white blood cells showed increase approximately synchronously with the paroxysm, small lymphocytes and polymorphonuclears were normal, the large lymphocytes were increased, but there was no evidence of eosinophilia. The coagulation time of the blood was shortened and its alkalinity lowered.

It is not obvious what deduction, if any, can be made from the above observations, but in a disease as obscure as epilepsy all accurate contributions to the pathology are welcome as possible future sources of light in the therapy.

CITRATED MILK FEEDING FOR INFANTS.

There has been of late a good deal of discussion with regard to citrated milk feeding for infants. Dr. F. J. Boynton was the first to work out and publish a paper on this form of feeding, and in the *Practitioner* for June, 1916, he has a short paper on the subject, in which he reiterates several of his former conclusions. He is of the opinion that it is a practical error to advocate placing infants on citrated whole milk from the first, as he thinks there is too much risk in such a course. Diluted milk should be used until the infant's reaction to cow's milk has been tested, and then the strength of the milk should be quickly increased. Citrated milk is valuable for correcting milk dyspepsia. Nevertheless, its routine and prolonged use are not advisable. Moreover, the use of very diluted milk with large quantities of citrate of sodium may result in general anasarca and convulsions. Sometimes it produces instant diarrhea, but Boynton remains convinced that his original contention that it has a tendency to produce constipation is correct. The citrate should be increased in proportion to the milk, and not to the mixture of milk and water. Boynton especially emphasizes the point that sodium citrate should never be given to a healthy child of eight or nine months as a routine practice, and when given he prefers a solution to tablets. The commencement of hand feeding should always be cautious. Small infants should not be started on citrated whole milk. In short, when used judiciously and discreetly sodium citrate in many instances is valuable in the feeding of infants, but care must be taken not to overdo the practice or to use the drug prematurely.

News of the Week.

Medical Preparedness.—Col. Jefferson R. Kean, Medical Corps, U. S. A., director general of military relief for the American Red Cross, states that the most important work which has probably ever been undertaken by the American Red Cross for the assistance of the medical service of the army is now being done in the organization of base hospital units from the personnel of the larger civil hospitals in this country. These base hospitals, which embrace much of the best professional talent in the country, are intended to be transported on the outbreak of war to the seat of military operations, where they will be located at the city which is selected to be the military base. One of these is needed for each 20,000 men brought into service. They receive the sick and wounded coming from the field hospitals at the front, and in them the wounded soldier in his journey to the rear first finds a comfortable bed and trained nurses. Thirteen base hospitals with skilled personnel are now organized and seven more are in process of organization. Each base hospital is equipped to receive 500 patients. Although organized by the Red Cross, they are not administered by it, but when called into active service pass under the exclusive authority of the War Department and become a part of its medical service. The medical officers are given military commissions in the Reserve Corps, and receive volunteer commissions when called into active service. The nurses in the same way belong to the Red Cross Nursing Service, and in time of war become a part of the Army Nurse Corps. The organization in

time of peace of these large and complex units will place at the disposal of the Government immediately on the outbreak of war organizations which it would require many weeks to create and equip, and offers our soldiers from the first the finest medical talent in the country. The following are the locations of these hospitals and the heads of their various services:

Presbyterian Hospital, New York City.—Director and chief of surgical service, Dr. George E. Brewer; principal assistant, Dr. Alfred Stillman; chief of medical service, Dr. Warfield T. Longcope; chief of laboratory service, Dr. Karl M. Vogel; chief nurse, Miss Anna C. Maxwell.

Mount Sinai Hospital, New York City.—Director, Dr. N. E. Brill; chief of surgical service, Dr. Howard Lilienthal; chief of medical service, Dr. R. Weil; chief of laboratory service, Dr. George Baehr; chief nurse, Miss Elizabeth A. Greener.

Bellevue Hospital, New York City.—Director and chief of surgical service, Dr. George David Stewart; chief of medical service, Dr. Van Horne Norrie; chief of laboratory service, Dr. Charles Norris; chief nurse, Miss Clara D. Noyes.

New York Hospital, New York City.—Director and chief of surgical service, Dr. Charles L. Gibson; chief of medical service, Dr. Lewis A. Conner; chief of laboratory service, Dr. William J. Elser; chief nurse, Miss M. H. Jordan.

New York Postgraduate Hospital, New York City.—Director, Dr. Samuel Lloyd; chief of surgical service, Dr. Edward W. Peterson; chief of medical service, Dr. Arthur F. Chace; chief of laboratory service, Dr. Ward J. MacNeal; chief nurse, Miss Amy Patmore.

Brooklyn, N. Y., for Navy.—Director and chief of surgical service, Dr. W. B. Brinsmade; chief of medical service, Dr. Luther F. Warren; chief of laboratory service, Dr. Robert F. Barber; chief nurse, Miss Frances van Ingen.

Massachusetts General Hospital, Boston, Mass.—Director, Dr. Frederic A. Washburn; chief of surgical service, Dr. George W. W. Brewster; chief of medical service, Dr. Richard C. Cabot; chief of laboratory service, Dr. J. Homer Wright; chief nurse, Miss Sara E. Parsons.

Boston City Hospital, Boston, Mass.—Director, Dr. J. J. Dowling; chief of surgical service, Dr. Edward H. Nichols; chief of medical service, Dr. John Jenks Thomas; chief of laboratory service, Dr. Arial W. George; chief nurse, Miss Emma M. Nichols.

Harvard University, Mass.—Director and chief of surgical service, Dr. Harvey Cushing; chief of medical service, Dr. Roger Lee; chief of laboratory service, Dr. Richard P. Strong; chief nurse, Miss Carrie M. Hall.

Lakeside Hospital, Cleveland, Ohio.—Director, Dr. George W. Crile; chief of surgical service, Dr. W. E. Lower; chief of medical service, Dr. C. F. Hoover; chief of laboratory service, Dr. H. T. Karsner; chief nurse, Miss Grace Allison.

Rochester, N. Y.—Director, Dr. John M. Swan; chief of surgical service, Dr. C. W. Hennington; chief of medical service, Dr. William V. Ewers; chief of laboratory service, Dr. C. C. Sutter; chief nurse, Miss Emma Jones; assistant, Miss Jessica Heal.

Johns Hopkins Hospital, Baltimore, Md.—Director, Dr. Winford Smith; chief of surgical service, Dr. J. M. T. Finney; chief of medical service, Dr. T. C. Janeway; chief of laboratory service, Dr. T. R. Boggs; chief nurse, Miss Bessie E. Baker.

Harper Hospital, Detroit, Mich.—Director, Dr. Angus McLean; chief of surgical service, Dr. C. D. Brooks; chief of medical service, Dr. B. R. Shurly; chief of laboratory service, Dr. P. M. Hickey; chief nurse, Miss Emily McLaughlin.

The names of the heads of the German and Lincoln Hospital units in New York have not been announced at this writing.

Mr. Irving T. Bush has relieved the embarrassment of the Red Cross in regard to space for storing the equipment of the five base hospitals now being organized in New York in behalf of our own army and navy by offering to provide for three of these units at the Bush Terminal.

Death Rate in New York.—The death rate in New York City for the week ending June 17 was 12.36 per 1,000 of population, representing a total of 1,324 deaths, as compared with a rate of 13.28 for the corresponding week of 1915. This decrease was due chiefly to the lessened mortality from the acute infectious diseases—measles, scarlet fever, diphtheria, croup, and whooping-cough—and from lobar and bronchopneumonia. There was, however, an increase in the number of deaths due to heart disease, Bright's disease, and pulmonary tuberculosis. For the first twenty-five weeks of 1916 the death rate was 14.92, or 0.29 lower than for the same period last year.

Medical College Commencements.—At the ninety-first annual commencement of Jefferson Medical College, Philadelphia, held on June 3, the degree of doctor of medicine was conferred on 162 graduates of the school. Dr. W. W. Keen addressed the class on "The Doctor's Duty."

The thirty-sixth and final commencement exercises of the Medico-Chirurgical College, Philadelphia, were held on June 9, when the medical degree was conferred on eighty-three graduates. The college has been merged with the medical department of the University of Pennsylvania.

Six graduates in medicine received the doctor's degree at the 216th commencement of Yale University on June 21. Dr. Arthur Dean Bevan, professor of surgery in the Rush Medical College, Chicago, and chairman of the council on medical education of the American Medical Association, received the honorary degree of master of arts; the same degree was given to Dr. David Russell Lyman, head of the Gaylord Sanatorium, Wallingford, Conn., and on Dr. Theobald Smith of the Rockefeller Institute of Medical Research was bestowed the honorary degree of doctor of science. The Yale Corporation has announced that hereafter a limited number of graduates of approved colleges for women will be admitted to the Yale School of Medicine.

Harvard University at its annual commencement on June 22 bestowed the degree of doctor of medicine on sixty-three graduates of the medical school, and the degree of doctor of dental medicine on forty-five graduates. Dr. W. G. Smillie and Dr. Ralph Mellon received the degree of doctor of public health, and Dr. Richard Pearson Strong, professor of tropical medicine in the Harvard University Medical School, received the honorary degree of doctor of science.

Personals.—Dr. Edward Perkins Carter, professor of medicine in the medical department of Western Reserve University, Cleveland, Ohio, received the honorary degree of master of arts from Williams College, Williamstown, Mass., on June 21.

Dr. Joseph A. Andrews of New York and Los Angeles, Cal., sailed from New York on June 20 for Labrador, on his sixth annual trip to treat at Gren-

fell Mission natives of Labrador who are suffering from eye troubles.

Dr. Allen G. Rice of Springfield, Mass., has for the second time within four years been awarded the prize of $200 offered annually by the Caleb Fisk estate of Providence, R. I. The subject for this year was "Diagnostic and Prognostic Value of Blood Pressure Determinations."

Dr. Charles L. Gibson, director and surgical chief of the New York Hospital Red Cross unit, sailed for Europe on Saturday last.

Civil Service Examination.—The New York Municipal Service Commission, Municipal Building, Manhattan, will receive applications until July 5, 1916, from candidates for the position of pathologist in the city employ. One vacancy exists at present in the Department of Public Charities, Kings County Hospital, Brooklyn, at a salary of $1,500 per annum without maintenance. Application blanks will be mailed upon request, but no applications will be accepted at the office of the Commission after 4 o'clock P.M. on the date mentioned. Candidates must be over twenty-one years of age and have the degree of M.D. from an approved institution. The duties of the pathologist include the performance of autopsies, the microscopical diagnosis of tissues, and bacteriological diagnosis and clinical pathology; and a practical test will be held in the laboratory at which the candidates will be required to demonstrate their ability to perform the work as above outlined.

Navy Medical Corps.—The next examination for appointment in the Medical Corps of the United States Navy will be held on or about August 7, 1916. The first stage of the examination is for appointment as assistant surgeon in the Medical Reserve Corps; the successful candidate then attends the course of instruction at the Naval Medical School, beginning October 1, 1916, and during this course receives a salary of $2,000 per annum, with allowance for quarters, etc. At the end of the course, if he passes an examination in the subjects taught, he is commissioned an assistant surgeon in the navy to fill a vacancy. Applicants must be citizens of the United States and must submit satisfactory evidence of preliminary education and medical education. Full information with regard to the physical and professional examinations, with instructions how to submit formal application, may be obtained by addressing the Surgeon General of the Navy, Navy Department, Washington.

Grading of Restaurants Continues.—The Health Department continued during the past week its work of inspecting and grading the restaurants in New York City, although no figures have been given out, the Department having determined, in order not to be unfair, not to grade a restaurant until after reinspection. This will meet the objection that minor violations have resulted in some of the recent "bad" gradings. The Department has received indorsements of its plan from the State Food and Drugs Commissioners of North Dakota and Indiana, in both of which States similar grading has been carried out.

Poliomyelitis Epidemic.—During the past few weeks an unusually large number of cases of poliomyelitis have been reported, especially from the section bounded by Henry Street and Seventh Avenue, Baltic Street and First Street, and occurring chiefly among Italians. The Department of Health is having made a house to house canvass in each block in which there is known to be a case of the disease, and the Acting Commissioner has addressed a letter to every Brooklyn physician, calling attention to the existence of the disease, the methods of diagnosis, and the possible modes of infection, and asking for the co-operation of the profession in controlling the outbreak.

A Decision Against the American Medical Association.—The long-drawn out trial of the Chattanooga Medicine Company's suit against the American Medical Association for libel has at last ended with a verdict against the Association. The *Journal* had characterized one of the products of the Medicine Company as "booze," "a tipple," and "a worthless fraud." The trial, which was held in Judge Landis' court in Chicago, lasted three months and must have cost the Association a very large sum.

Obituary Notes.—Dr. LAWRENCE THOMAS AITKEN of Brooklyn, N. Y., a graduate of the Long Island College Hospital, Brooklyn, in 1908, pediatrist at the Coney Island Hospital, and dermatologist at the Polhemus Clinic, died at his home on June 18, aged 32 years.

Dr. EUGENE ALBERT GILMAN of Boston, Mass., a graduate of Harvard University Medical School in 1872, and a member of the Massachusetts Medical Society and the Suffolk County Medical Society, died at his home, after a lingering illness, on June 17.

Dr. FREDERICK BUELL WILLARD of Hartford, Conn., a graduate of the University of Vermont, College of Medicine, Burlington, in 1900, a member of the American Medical Association, the Connecticut State Medical Society, the Hartford County Medical Society, and the American College of Surgeons, and a surgeon on the staff of the Hartford Hospital, died at the hospital, following an operation for appendicitis, on June 16, aged 43 years.

Dr. JOHN OWEN SMITH of South Canterbury, Conn., a graduate of the Eclectic Medical College of the City of New York in 1882, died recently at his home, aged 76 years.

Correspondence.

THE SARATOGA CO_2 BATHS.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—At the annual meeting of the Saratoga Springs Medical Society held on May 25, 1916, Conservation Commissioner George D. Pratt, under whose department the management of the State Mineral Water Reservation at Saratoga Springs has recently been placed, was a guest of the society and addressed the meeting on the above subject. He said in part as follows:

> I have evolved certain fundamental policies with regard to this reservation which I am very anxious to make clear, not only to the members of your own society but also to the medical profession at large. No more fortunate time for expressing these principles could be found than this evening, when what I have to say can be addressed to you personally and through you to your brothers in the profession throughout the entire United States. In full assurance that the force of my statement will be thoroughly appreciated, I can say to you that the highest development of the springs at Saratoga and the greatest realization by the people of the healing virtues in their waters can be brought about only by whole-hearted cooperation between the physicians themselves and the State commission that is charged with the control of these natural resources.
>
> The waters of the springs are good of themselves, and in many cases may be taken freely without medical direction. This is particularly true of the table waters, of which Saratoga offers a wonderful supply. When we

turn to the medicinal springs, however, we are brought face to face with the incontrovertible medical fact that in a large number of diseases the greatest good from these waters can be obtained only through careful courses of treatment prescribed and carried out in accordance with the tested principles of medical therapeutics. It is well understood by physicians that every case of disease and of lowered efficiency, such as can be benefited by the opportunities presented at Saratoga, has its own individual characteristics, and that these characteristics, these organic and constitutional conditions, can be accurately determined only by expert medical diagnosis. It accordingly follows that correct application of the principles of medical therapeutics to each individual case can be made only by a physician. In fact, though I am no physician, I believe that I am not far from the truth when I state that persons who without the advice of a competent practitioner undertake courses of treatment for the serious maladies that bring many of them to the baths and springs at Saratoga are taking very grave and unwarrantable chances. If this is true, it is clearly evident that right utilization of the medicinal springs at Saratoga can be brought about only through coordination of the State's administrative control with the practice of the medical profession.

It is in the highest degree important that the Conservation Commission, in its conduct of the great natural resources found here in such lavish abundance, shall appreciate fully not only the material, physical requirements for taking the cures that these waters offer, but also the ethical obligations that are involved in the exploitation of the springs. I speak of these ethical obligations in the medical sense. In the advertising and sale of the purely table waters, such as the Soft Sweet Spring water, and the other waters for which curative qualities are not claimed, the obligations imposed upon the commission are the usual moral obligations of honest and conservative business. With the development of the medical springs, however, whether their waters are used for baths or for drinking, there is imposed upon the commission a further obligation which you physicians, if not all laymen, understand as the obligation of medical ethics. This obligation the commission will endeavor to appreciate and adhere to. Saratoga holds no cure-all. But for certain diseases and for certain functional disturbances, fostered by the pace of our modern, high-pressure civilization, its springs do indeed run with an elixir of life and hold as much of the power of rejuvenation as any fountain of youth yet discovered. In their more extensive development no false or extravagant claims must be made for them. They need no such exploitation. But in a thoroughly broad-minded and ethical spirit the boons that they offer must be made increasingly available to the entire public in their pure and unchanged natural condition.

It is now of immediate importance that the medical profession at large and the people of Saratoga and of the State and nation understand the firm resolve of the commission, and, behind the commission, of the State administration, as vouched to you by Governor Whitman the other day, to work steadily and consistently, and above all ethically, for the higher development of this wonderful health resort. There has grown up in the public mind, and in the minds of some of the medical profession, an idea that the waters of Saratoga are adulterated or altered in some degree. If this were true it would be equivalent to an admission that the waters of Saratoga are either not all that is claimed for them or else they have been lessened in value by alteration or adulteration. We know, on the authority of the very highest medical opinion, that the unchanged waters of the springs, as they flow naturally from the earth, are equal, if not superior, in their medical qualities to those of any other known springs in the world. To adulterate them is unthinkable to any right-minded person, and to alter their chemical content is quite unnecessary. I wish to state to the medical profession on this occasion that the policy of the Conservation Commission will be to conserve the springs in their natural state and to give both the baths and the waters in the same natural condition that they are in when they come out of the ground. If any individual physician wishes to prescribe them in altered form for an individual patient this will be entirely upon his own responsibility and will affect no other than his own individual patient. The waters of Saratoga are Saratoga waters. As such they are widely and favorably known for their efficacy in the treatment of certain disorders. To endeavor to identify them as to their chemical make-up with the waters of other springs is to endeavor to make them shine by reflected light. It is the belief of the commission that they need no such illumination. To change their make-up artificially in order to make them more nearly conform to the chemical formula of springs in other places is to assert that their established reputation has been built upon no firm foundation in the past. Such a statement would be untrue. Saratoga offers its own gift to the world; a gift that, in the opinion of the most capable specialists, is destined to place Saratoga still farther in the lead as one of the world's great benefactions. Believing fully in the correctness of this prophecy, the Conservation Commission is determined that Saratoga's position shall be taken by Saratoga herself because of the merits that it possesses, and not because of artificial or transplanted merits or reputation. In this endeavor the commission asks the cooperation of the medical profession.

The force and wisdom of the policy herein outlined by Commissioner Pratt are most commendable. The local medical society through many of its members expressed sincere and hearty accord with the Commissioner's ideas. The medical profession of Saratoga Springs realize that the Saratoga mineral waters have in the past with careful and scientific administration given most excellent and decided results in pathological and functional disorders and now with the increased efficiency of these waters and the added facilities for their administration made possible by state ownership and control, these therapeutic results have been increased several fold.

The physicians of Saratoga Springs decry most sincerely the adulteration of these waters for bathing purposes unless it be in exceptional cases where it should be left to the judgment of the individual physician to determine what additions shall be made and in what quantities and these additions should only be made on special prescription. They do not in any sense favor the routine addition of any chemicals to the natural Saratoga waters, believing that these waters in themselves with their supersaturation with carbonic acid gas are eminently efficient without any addition and that they should stand on their own merits for therapeutic effect.

The use of the term "Nauheim Bath" is somewhat misleading as every so-called "Nauheim Bath" throughout the world varies from all the others and the use of that name as applied to the Saratoga waters should be discouraged. The local profession prefer the term "Saratoga CO_2 Mineral Baths." Following the discussion of the subject the following resolution was unanimously adopted:

"*Whereas,* after an experience covering a considerable period, during which observations have been made of several thousand baths administered to a large number of patients at Saratoga Springs with the use of unaltered natural mineral water:

"*Resolved,* that it is the deliberate and emphatic expression of the conviction of the members of the Saratoga Springs Medical Society that for series of successive CO_2 mineral baths given systematically, our natural Saratoga Springs mineral water, as now supplied in the tubs of the State bath-houses, with its dissolved gas retained in supersaturation, is fully efficient; and further, that it should be used for such series of baths without the addition of any salts, chemicals or other substances, unless such additions are plainly and explicitly ordered in the prescription of the physician."

It is believed that when this matter is carefully analyzed this position in regard to the baths at Saratoga Springs will meet with the approval of the profession of the State as well as of the nation.

OFFICERS OF THE SARATOGA SPRINGS MEDICAL SOCIETY.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

GENERAL MEDICAL COUNCIL—EDUCATION COMMITTEE —TEACHING ETHICS—FORENSIC MEDICINE—DENTAL COMMITTEE—PUBLIC HEALTH, PHARMACOPŒIA AND OTHER COMMITTEES—GENERAL MAXWELL'S TRIBUTE—KILLED AND WOUNDED—DISTINGUISHED SERVICE.

LONDON, June 10, 1916.

THE General Medical Council has held its 103rd session, extending over five days. Much of the business is formal but necessary and would not interest your readers, but there are some subjects which may claim mention. Thus penal cases occupy a good deal of time and result in a few names being removed from the register for "infamous conduct in a professional respect," the most frequent offence being that of "covering" illegal practice. Generally, it is a nurse who has thus been enabled to abuse her position and the council "takes a very grave view" of the danger from the public point of view of practitioners lending their names for this purpose. Nevertheless, when cases are proved the judgment too often only amounts to a brief suspension which, in such circumstances, may not be so severe as it looks, and those are not altogether unreasonable who urge that the full penalty in a few cases would be a more efficient deterrent.

The report of the Education Committee refers to the ethical relationships of practitioners to the State, to their patients, and to each other. At their appointment they were directed to make such inquiries as they deemed advisable on these matters. A letter addressed to all the teaching bodies elicited the information that the subject is dealt with as a part of the regular work in the colleges—sometimes in the courses of forensic medicine and public health or in other classes; sometimes in special lectures. But in a number of institutions no regular instruction has heretofore been provided on the subject. The committee consider that this neglect should not continue though they recognize that great variety may exist in the arrangements made by various bodies. They propose that a general recommendation dealing with the teaching of medical ethics be added to the resolution of the General Medical Council in regard to professional education, as follows: "Instruction should be given in the courses of forsenic medicine and public health, or otherwise, on the duties which involve upon practitioners in their relationship to the State, and upon the generally recognized rules of medical ethics. Attention should be called to all explanatory notices on these subjects issued by the General Medical Council."

The report of the Dental Education and Examination Committee was received and approved after some discussion. Reports from the committees on Public Health, the Pharmacopœia and Students' Registration were also received, approved and entered on the minutes.

General Maxwell has paid a striking tribute to the doctors and nurses who rendered their valuable services during the late disturbances in Dublin and particularly those who exposed themselves to heavy fire in attending to and removing the wounded. Also to members of the Red Cross and St. John's Ambulance Societies, as well as the numerous medical men and private persons who gave assistance to these associations or in other ways helped in the work, especially those who placed their houses at the disposal of the military medical staff for use as dressing stations. In numerous instances such services were rendered in circumstances involving great inconvenience and even personal risk.

The war office has issued dispatches from the commanders at the front in which a number of medical officers are mentioned for distinguished and meritorious service.

The King has conferred the D. S. O. on Captain T. Lewis Ingram, R. A. M. C., who collected and attended wounded under very heavy fire and has been conspicuous for bravery throughout the war; also on Captain Brash, B. B., who, under heavy shell fire, assisted by two men, extracted the wounded at an artillery dug-out and administered first aid; on Captain Woodhouse, M. B., Captain Hart, M. B., and Lieutenant Knight, M.D., who acted in the same courageous way. The dispatches state that all branches of the medical services deserve the highest commendation for the successful work done by them both at the front and on the lines of communication. The sick rate had been low and there had been no epidemic. Enteric fever had almost disappeared before the energetic preventive measures carried out. The results of exposure in trench warfare in the winter were considerably restrained by the precaution of the regimental medical officers. The wounded were promptly and efficiently conveyed to the base. The cooperation between officers of the regular medical service of the army and members of the civilian medical body who patriotically assisted them contributed to the prevention of disease and the successful treatment and comfort of the sick and wounded. The value of the work in the central laboratory and of that done by the chemical advisers with the armies in investigating into the nature of gases and other new substances used in hostile attacks should not be overlooked nor should the means of protecting our troops against them.

In the Franco-Prussian War, out of 4062 German doctors with the army only 9 were killed and 69 wounded; but in the present war, up to January 15, 56 German doctors have been killed, 216 wounded, 40 made prisoners, and 94 are missing, while 29 have died of disease or wounds, 5 have met with accidents, and 2 are invalided. These figures are out of a total number of about 12,000 actually with the army and do not include men in the military hospitals, nor about 10,000 employed in reserve hospitals, sanatoria, prisoners' camps, and ambulance trains. As Germany has about 32,000 medical men, if these figures are correct, it would seem that only about 8,000 would be available for ordinary civilian practice.

Progress of Medical Science.

Boston Medical and Surgical Journal.

June 15, 1916.

1. Respiratory Exchange, with a Description of a Respiratory Apparatus for Clinical Use. Francis C. Benedict and Edna H. Tompkins.
2. Studies of the Basal Metabolism in Disease and Their Importance in Clinical Medicine. J. H. Means.
3. The Physicians and the Prevention of Industrial Accidents. Herbert J. Cronin.
4. Memorial Address. Benjamin E. Cotting.
5. Two Cases of Syphilis of the Lung. Abner Post.

1. Respiratory Exchange, with a Description of a Respiratory Apparatus for Clinical Use. — Francis C. Benedict and Edna H. Tompkins call attention to the fact that many clinicians are perhaps not aware that a loss in weight, especially an initial loss in weight,

may be largely due to a loss of water from the body, even with patients not edematous. Furthermore, they may have no knowledge as to whether the loss consists of fat, muscle, or carbohydrate. A loss in weight due to a loss of a specific material may vary in its interpretation according to the character of the material; thus a loss of muscle, and particularly a loss of carbohydrate, would have a far greater significance than a loss of fat. A definite knowledge of the character of the loss of weight may be obtained by a study of the respiratory exchange. In pathological cases it was distinctly of importance to know whether or not the demand for nutriment, as indicated by the total amounts of material consumed in the body, is met by the supply. Observations of the respiratory exchange will show very quickly the demand for energy under the conditions of observation, and thus the clinician will be able to adjust without delay the supply to the demand. The majority of the earlier methods of studying the respiratory exchange were, for one reason or another, precluded from general acceptance in clinics and an attempt was made to broaden the field of study and increase the potentialities, by devising, constructing, and testing a relatively simple apparatus called the "universal respiration apparatus." With this apparatus it was possible to measure the carbon dioxide output and the oxygen intake with almost as high a degree of accuracy as with the costly calorimetric respiration chambers. Before describing the apparatus the writers define exactly what is meant by the terms "respiratory exchange" and "respiratory quotient," consider their relation to the heat production, and outline the fundamental principles underlying a study of the respiratory exchange and the essentials for an apparatus designed for use in pathological cases. The detailed description of this apparatus will be published later.

2. **Studies of the Basal Metabolism in Disease and Their Importance in Clinical Medicine.**—J. H. Means defines what is meant by calorimetry, and explains the methods of calculation by which the respiratory quotient and heat production are obtained. He reviews various studies of the basal metabolism made in the medical wards of the Massachusetts General Hospital, a particular study having been made of thyroid disease and obesity. He lays emphasis on the following points. 1. Basal metabolism can be readily studied in a hospital clinic with a comparatively simple apparatus. 2. The normal basal metabolism is a fairly constant affair, and hence wide variations from it in disease are of interest to the clinician. 3. A marked rise occurs in hyperthyroidism. 4. A marked fall occurs in hypothyroidism. 5. In regard to hyperthyroidism it seems probable that the basal metabolism furnishes (*a*) The best index as to the severity of the disease, and hence is a quantitative means of following the course and of judging of the effectiveness of treatment; and (*b*) A valuable aid in differential diagnosis. 6. Enormous grades of obesity are possible in the presence of a normal basal metabolism. 7. When a reduction in the metabolism was found in obese subjects there was also clinical evidence of defective internal secretion. 8. A clearer conception of the food requirements in disease is furnished by the basal metabolism than by any other factor.

3. **The Physician and the Prevention of Industrial Accidents.**—Herbert J. Cronin believes that the physician should take a more active interest in the campaign for the prevention of industrial accidents. He points out that the physician is in a position to get the true history of how the accident occurred, look into the physical condition of the patient and decide for himself from the injury how it may have been caused. The recurring cases will be strongly brought to his attention. The youngest interne at any of the metropolitan hospitals quickly recognizes by their frequent occurrence the causes of the common traumatisms; he knows the crush from the printing press, the mangling of gears, the buzz-saw fingers, and burns from molten metals. The doctor can inspect the site of the accident before the real cause of the injury such as an oily floor or a broken board, is removed. The family physician of the manufacturer can draw attention to the reforms needed and give advice. Technical knowledge is not necessary in giving advice for the correction of a large number of accidents. Many of the accidents are caused by such simple things as obstructions, unguarded pits, or floor openings. The writer considers more in detail defects in machinery and other factors that are responsible for a large number of accidents and says it has been shown that after all the practical devices have been put on machines only about 35 per cent of accidents can be so prevented. In order to supplement the work, every plant should start a safety organization among its employes. He describes a plan for such a safety organization which will not increase the pay-roll, except in large plants where one employe is designated to be a safety inspector and spends his entire time at the work. In closing, it is stated that the by-products of industrial warfare are worse than those of real warfare and that the medical profession should act as pioneers in this new work as they have done in nearly every other social reform.

5. **Two Cases of Syphilis of the Lung.**—Abner Post reports these two cases, both of which were syphilitic, and in neither of which were tubercle bacilli found. The resemblance of the radiograms in these two cases is striking. From these cases the writer believes it is justifiable to say that disease of the lung, in which consolidation is found in unusual positions, or limited entirely to one lung and in which tubercle bacilli have not been found, may be considered suspicious of syphilis. If the Wassermann is positive the suspicion is much greater and may almost be regarded as a certainty. It is certain that consolidation in unusual positions, with the absence of tubercle bacilli and the presence of a positive Wassermann, does not permit the diagnosis of tuberculosis. These cases show also the important fact that syphilis of the lung occurs in hereditary cases, that is, among the young, the very individuals who are most subject to tuberculosis.

2. **Failures in Diagnosis.**—William S. Gordon gives a comparison of physical and laboratory methods, and sums up by stating the following: The chief causes of errors or failures in diagnosis are ignorance or neglect on the part of the physician; the partial or incomplete employment of the aids afforded by science;

the failure to make routine examinations; the failure to correlate laboratory and physical findings; exceptions to the laws governing diagnosis and pathology; the limitations of scientific knowledge; the impracticability at times of using all of the diagnostic methods; the failure of the patient to submit to the requirements of the physician; the direct or indirect influence upon patient and physician of the erroneous expressions of the laity. Science is rapidly advancing in all of its branches. Diagnosis is becoming more and more accurate, while the doctor is becoming more highly educated. When the public awakes to a realization of the many difficulties which beset the pathway of the medical man, and when it ceases to place him on a level with the charlatan, it will be surprised at the comparatively few mistakes which the physician makes and at the large number of successes which can be placed to his credit.

3. **Focal Sepsis.**—Judson Daland considers a cause of constitutional disease from the viewpoint of the internist and offers the following conclusions: 1. Chronic focal sepsis is known to be one of the causes of acute and chronic arthritis, periarthritis, arthritis deformans, osteitis, endocarditis, pericarditis or myocarditis, endarteritis, acute and chronic parenchymatous nephritis, cholecystitis, cholelithiasis, gastric and duodenal ulcer, appendicitis, meningitis, thyroiditis, neuritis, oophoritis, ocular diseases, furunculosis, and is the recognized cause of other diseases. 2. The results of chronic focal sepsis are due to the varying virulence of the microorganism, the duration of the focus, the quantity of microorganisms and toxins entering the circulation, the rapidity of absorption, the integrity of the tissues, and the susceptibility or immunity of the patient. The rôle of toxemia is not fully understood. 3. The usual location of chronic focal sepsis in the order of frequency is the mouth, the tonsils, and the sinuses. 4. The diagnosis of chronic septic focus is sometimes easy, but more often difficult. A common error is to recognize only one focus when more than one exists, and this is especially true of the teeth. Loose, dead, capped teeth and those containing large fillings, or those connected with bridges or artificial dentures, are frequently septic and should be explored. The mouth should be carefully examined for pyorrhea or pyorrheal pockets. The diagnosis of mouth sepsis should be made by a dentist especially trained for this work, and a roentgenograph is always necessary. A tonsil may appear normal and yet contain an abscess or be infected. A partial removal of a tonsil may cause a septic focus by sealing crypts and follicles. The adenoid structure in the supratonsillar fossa may be infected. A sinus may appear normal and a second examination show suppuration. This is especially true of the ethmoid and sphenoid. The virulence of the microorganism, rather than the size of the focus, is important. 5. Success in treatment of constitutional diseases secondary to focal sepsis depends upon the diagnosis and removal of the focus or foci of infection. Temporary improvement with relapses may be expected when the septic focus is only partially removed. After removal of the focal sepsis recovery may be hastened by personal and general hygiene. It is believed by those having experience that an autogenous vaccine hastens recovery. I have seen a number of patients make satisfactory recoveries without vaccines. The recognition of the principle of secondary systemic infection is one of the most important advances in medicine in recent years.

9. **Radium in Gastric Carcinoma.**—C. Everett Field approaches this theme with a degree of hopefulness that he trusts will not be considered unduly enthusiastic. Possibly there is no subject in medicine or surgery today that is receiving more attention at the hands of the scientific world than radium. To the credit of this element we must acknowledge that a large percentage of the early disappointments were due to the fact that insufficient doses and lack of purity of the elements were common. Radium does kill the cancer cells and exerts its power in direct accord with the accessibility of the mass. Superficial cancer is controlled and cured in fast increasing percentages. In the light of our present knowledge we place the rays as merely an adjunct to the knife. The London Radium Institute, in its report for 1913, says that "tabulated data on a total of 181 cases of cancer of the face, neck, and breast, show a total of 154 cases healed, and seventeen discontinued. Of the 154 listed as healed on January 1, 1911, at present 135 are still healed." Von Czerny of Heidelberg has reported observations in several thousand cases of gastric carcinoma. His experiences detail the direct application of radium, the use externally of radium compresses for the relief of pain, and the injection of soluble salts. With the later treatment, he avers that he has checked for a time active congestion, relieved the pain, and reduced stenosis to the point of allowing the passage of food.

1. Some of the Larger Problems of the Medical Profession.—Professor Rupert Blue. (See MEDICAL RECORD, June 17.)

2. Dispensary Abuse and Certain Problems of Medical Practice.—J. Whitridge Williams spoke on this subject at the one-hundred and eighteenth meeting of the Medical and Chirurgical Faculty of Maryland. He outlines the growth of the modern dispensary and pleads for the maintenance of dispensaries of the highest type, with the knowledge that the better they become, the greater will be the cry of the dispensary abuse, which to his mind will not disappear until the principles of medical practice in our larger cities have undergone reorganization. As a corrective of the present abuse of free operations by persons able to pay, he suggests that a mechanism should be devised for the investigation of the circumstances of the patient and the charging of an equitable fee by the institution. In many cases after charging such a fee for drugs and supplies nothing would be left for the surgeon, but in other instances a balance would be left for the payment of professional services. Naturally this would be so small that the operator could not accept it as a fee without a distinct loss of self respect, so that the question would arise as to its disposition. Such money along with other available funds could be utilized for the payment of moderate salaries to the members of the staff who do the work, with the understanding that such a salary was in lieu of all fees from patients, except those occupying private rooms at full rates. The author endorses the "diagnostic group plan" which is being used at the Massachusetts General Hospital, and suggests that a fee of $10 to $25 be charged for

the complete examination, and that the dispensary staff should be compensated either by fixed salaries or by a pro rata division of the fees after a proper deduction has been made for maintenance charges. He then considers the subject of health insurance and suggests that each insured family be allowed to choose as its medical attendant any physician on the panel of the insurance organization living within a certain radius. In cases of minor illness the patient would visit the physician in his offices or go to the dispensary, while in more serious cases he would go to the dispensary for diagnosis and treatment. If the patient were ill in bed he would be cared for at home by his medical attendant and a visiting nurse, or sent to the hospital if the physician deemed it advisable. Under such a system there would be no possibility for dispensary abuse as the expense would be borne by the insurance fund and indirectly by those insured, no matter whether the patients were treated at home or at the dispensary or hospital. Nor would the doctor suffer. As probably two-thirds of the residents of each district would be in the insured class, large numbers of physicians would be necessary for the conduct of the dispensary and hospital and as they would be paid for such services, as well as for visiting patients in their own homes, and would have no bad bills, they would probably consider it a matter of indifference where the patients were seen. This would mean that the great majority of physicians would become state officials and would devote their entire time or a great proportion of it to official duties.

3. **The Duodenal Tube as a Factor in the Diagnosis and Treatment of Gall-Bladder Disease.**—Max Einhorn emphasizes the advantages of direct examination of the bile in diagnosing gall-bladder disease. He says he had diagnosed probable cholecystitis by examination of the bile in conjunction with the usual symptoms in forty cases since May, 1914. Thirteen of these cases were operated upon. In the majority of cases in which turbid bile was found in the duodenum in the fasting condition, cholecystitis with gallstones is encountered. Turbid bile may exist, however, without gall-bladder disease when the liver itself is seriously diseased, or in stricture of the duodenum below the papilla of Vater. On the other hand clear bile may exceptionally be found in association with biliary calculi. There are then two possibilities: Either the gall bladder is not inflamed or the gall bladder is entirely filled with the calculi. In these cases no bile enters the organ and it therefore enters the duodenum in the same state as excreted by the liver. In a number of patients with cholecystitis an attempt was made to instil a weak solution of ichthyol or argyrol into the duodenum just above Vater's ampulla. The writer describes his method of doing this and believes that it possesses a distinct benefit. He has also carried out duodenal alimentation for the relief of gastric or duodenal ulcer; among them were quite a number of patients who had gallstones at the same time. The latter were benefited not only with regard to their digestive disorders but also in reference to their gall-bladder condition. This occurred in a striking manner with such frequency that he felt inclined to attribute to the duodenal alimentation the decidedly beneficial influence on the gall-bladder lesion. The essayist believes that duodenal alimentation will find an appropriate place in some forms of cholecystitis, particularly when complicated with ulcers of the stomach or duodenum.

4. **Acidosis in Diabetes.**—R. T. Woodyatt discusses acidosis in general, the origin of the acidosis compounds, conditions favoring their appearance, acidosis in fasting, and states that acidosis in diabetes develops under exactly the same fundamental conditions which cause this condition in non-diabetics. There happens in the severe cases of diabetes a rate of fatty acid metabolism which in the absolute sense is not greater than what might occur in health but becomes excessive in proportion to the amount of oxidizing glucose and so acidosis develops. In order to check a diabetic acidosis, it is necessary to restore the proper ratio of fatty acid to glucose oxidation by reducing the fatty acid metabolism to whatever level is fixed by the existing rate at which glucose is oxidizing. In diabetes protein alone, if metabolized in sufficient amounts, may be productive of acidosis as well as fat, because, although protein in breaking down liberates plenty of glucose for the complete oxidation of its own ketogenic fraction, in diabetes not all the glucose so formed can be oxidized owing to the lessened ability of the body to split it open. Accordingly to check a diabetic acidosis it is necessary to reduce both the protein and the fat metabolism. Fasting, rest, and warmth accomplish this.

6. **Trench Foot Tetanus.**—George G. Davis and Joseph J. Hilton report a case of tetanus occurring as a complication of "trench foot" with a fatal outcome. In this case a prophylactic dose of antitetanic serum had not been given, and in view of the excellent results obtained by prophylactic doses in the wounded the writers conclude that it would be a reasonable rule in military surgery to consider all cases of trench feet as in a class with the wounded, and to give these patients also in every instance a prophylactic dose of antitetanic serum.

8. **An Unusual Stomach Case, with Roentgenographic Findings.**—George E. Brown reports this case which is of interest not alone because of its clinical rarity, but also from the fact that the roentgenologic findings were deceptive. The mass on the lesser curvature resembled the roentgenologic picture of penetrating ulcer, though no incisura was present. The clinical findings were also deceptive, namely, hematemesis, occult blood in stools, gastric pain, and vomiting. The writer says he can find no mention of any similar condition in the textbooks.

9. **Fecal Concretions of the Appendix.**—John Douglas and Leon Theodore LeWald state that in a small number of instances a fecalith of the appendix may be demonstrated by roentgenographic examination and that this fact must be taken into consideration in making an examination. Usually the passage of opaque ureteral catheters will be of the greatest assistance in differential diagnosis, but the two cases reported by Eastmond and Seelig demonstrate that even with this assistance a mistake may be made. As a further aid in Roentgen diagnosis, they would suggest that when the shadow is above the crests of the iliac bones, a *lateral* stereoscopic roentgenographic examination be made, preferably with an opaque catheter in the ureter on the suspected side. In a case recently examined in this way they were able to distinguish what is probably a calcified lymph node from a supposed ureteral calculus. If there is still doubt, a Roentgen examination, combined with an opaque meal or enema, may show the relationship of the suspicious shadow to the appendix or cecum. They call attention to the possibility of one encountering a left sided appendix due either to a non-rotation of the colon or to a complete transposition of all the viscera. LeWald has encountered the former condition in three persons, and the latter condition in twelve. A shadow on the left side, therefore, may represent a calculus in the appendix unless a Roentgen examination shows the cecum on the right side.

2. Arrangements for the Care of Cases of Nervous and Mental Shock Coming from Overseas.—William Aldren Turner gives information with reference to the arrangements that have been made for the care of soldiers sent home from overseas who are suffering from nervous shock, neurasthenia, and nervous breakdown. At the commencement of the war the cases of nervous shock and neurasthenia were transferred from over seas in company with medical and surgical cases, and were treated in the general wards of the hospitals at which they arrived, while the cases of mental disorder were transferred to the established institutions for the treatment of mental patients in the service of the army. The increase in the number of cases of this nature coming over in consequence of the severe fighting during October and November, 1914, made special provision for their treatment desirable. Plans were made so that upon the soldier's arrival at one of the British base hospitals abroad his condition was investigated by a special medical officer. The patient is then sent to a section of a hospital according as his symptoms are of a neurological or a mental character. Should he be suffering from transitory mental symptoms, which subside rapidly, he is transferred from the mental to the neurological section as soon as it is advisable to do so. In order to meet this class of cases special accommodation is now being provided at the base hospitals overseas, so that the patient may be placed under the most suitable circumstances for recovery. The patients are labelled for one of the clearing hospitals at home. On arrival at one of the clearing hospitals the patient is given treatment. If his symptoms are slight or transitory and disappear rapidly, he is sent on furlough and later is returned to light duty. On the other hand should the course of the disorder be less favorable, he may be transferred to one of the special hospitals for nervous diseases or to a special institution. In a general way the results of the treatment of the neurological cases showed 40 per cent of cases returned to light duty, 20 per cent invalided, and 20 per cent transferred for further treatment to the special institutions. The patients transferred to the mental hospitals are mostly of the certifiable type and include most of the severe forms of acute mental disorder. In accordance with accepted policy none of these patients are certified as of unsound mind. Each patient is given a reasonable period of treatment with a view to recovery. In consequence, however, of the accumulation of chronic and incurable cases which was observed a few months ago it was decided to discharge to asylums all cases of general paralysis of the insane, of epilepsy with insanity, and all patients who had been in asylums prior to enlistment. The percentage of cases of this kind returned to light duty was obviously small, from 10 to 15 per cent.

3. Congestion in the Treatment of Cerebrospinal Meningitis.—Duncan Forbes and Eveline Cohen report five cases of epidemic cerebrospinal meningitis in which congestion of the cerebral vessels was brought about by raising the foot of the bed. The foot of the bed was elevated so as to make an angle of from 14 to 23 degrees with the floor. The type of cases at first treated in this way were the class of cases that almost get over their illness, then become chronic and die. Later congestion was found useful in the earlier stages of the disease. If the head of the bed was raised too high there might be severe headache and persistent vomiting due to too great congestion and its results. In such cases if the bed was lowered and the tension relieved by puncture the patient usually recovered. As different cases require varying degrees of stimulation, no hard and fast rule can be laid down as to the height to which the foot of the bed should be raised.

4. The Treatment of Gunshot Wounds by Packing with Salt Sacs.—Alfred J. Hull says that the treatment of septic wounds by a pack which is allowed to remain in the wound for several days is so opposed to the usual teachings of surgery that at first sight its utility may be doubted. Nevertheless such treatment has proved one of the most effective methods of dealing with septic wounds during the present war. It has also been found to be one of the most generally applicable procedures for the treatment of secondary hemorrhages. The sacs are made of gauze in several sizes, filled with salt, sterilized in an autoclave, and stored ready for use. The effect of the salt bag is to form a concentrated solution of salt which promotes the resolution of inflammatory induration and aids the separation of dead tissue by solution of coagulated lymph. If the wound is clean the sacs are removed in from five to ten days, and treatment by normal saline solution. This method of treatment saves the patient the inconvenience of frequent dressing and forms an efficient means of preventing hemorrhage.

5. The Anatomical Position of Localized Foreign Bodies.—James Metcalfe and Ernest N. Keys-Wells call attention to the great improvements in detail and technique and the various forms of new and elaborate apparatus that have been evolved in order to produce greater accuracy in exact localization, and give their method of localizing foreign bodies in some of the important positions. The results have been arrived at by the use of a long needle on a handle and measuring the depth inserted when the bony point under investigation is reached. This method was supplemented by taking a double image of the various regions on one plate and estimating the depths of the body point as for a foreign body. No attempt had been made to give the positions in the leg or arm. A tales gives the various parts examined. The following are examples of anatomical depths estimated from the measurements and given to various surgeons.

1. Rifle bullet lying in wall of pericardium, the point 2 inches and the base 1½ inches from a mark on the front of the chest. Successfully and easily removed.

2. Small metallic fragment 2 inches deep to a mark on the front of the thigh on a level of the lesser trochanter, stated to be lying between adductor brevis and adductor longus. Removed without difficulty.

3. Rifle bullet, the point 1¾ inches and the base 2¼ inches deep to a mark over the scapula, stated to be in the serratus magnus. Removed from that muscle.

4. Shrapnel bullet, 1 3/5 inches deep to a mark on the front of the chest just below the coracoid, stated to be immediately beneath the tendon of the pectoralis minor. Removed from that position.

1. The Louse Problem at the Western Front.—A. D. Peacock presents a morphological study of the *Pediculus humanus* or common body louse and the results of an investigation into the habits of this parasite. As a result of his experiments it was found that the longest period during which lice survived separation from the human body was nearly nine days. The maximum time during which eggs away from the body might remain dormant was found by Warburton to be about forty days. This was under laboratory conditions and the temperature fell at times below the freezing point. Similar experiments were carried out and samples taken from a shirt exposed thirteen days did not hatch after twenty-eight days' incubation. In applying this knowledge the important fact is that eggs on the clothing, particularly the outer garments, if not treated regularly by ironing or disinfection, are a possible source of infestation for as long as a month after laying. Also, the removal of the clothing from the body for a few days in order to kill the eggs and lice by exposure is not a practical scheme. The louse, therefore, is a parasite which is utterly dependent upon man's blood for sustenance and man's body and clothing for prolonged, prosperous longevity and reproduction. The louse adds greatly to the troubles of the soldier at the front largely because of its interference with sleep which results in impaired vitality and mental weariness.

2. The Soldier's Foot and the Treatment of Common Deformities of the Foot.—Robert Jones expresses surprise at the number of men with claw-feet that have been passed into the army, and at the fact that many such cases have found their way to the front after the vigorous initial training which the recruit undergoes. Sooner or later these men gravitate to the hospital and few of them return to the ranks as efficients. A patient with this condition of the foot is quite unfit for military service, and should never be accepted as a recruit. Clinically the condition presents five degrees or stages. The progress of the development of the deformity from one degree to another, though often continuous, is frequently arrested in one of the early stages. Hallux rigidus, hallux valgus, and metatarsalgia are all frequently associated with flat foot. In connection with these conditions the author discusses the importance of correct position and free mobility of the great toe in marching. In young children of all races the great toe is directed slightly inwards towards the middle line of the body, in line with the anterior part of the inner longitudinal arch of the foot. In races who habitually go barefoot this position of the great toe is preserved in adult life. In civilized races—those, at least, who wear boots—the toes are often cramped into boots of unsuitable shape, so that the small muscles of the foot suffer atrophy from disuse, and the power to spread the great toe inwards in walking is much impaired. In a strong foot which has not been deformed by wearing pointed boots the great toe is spread inwards by the action of the abductor hallucis when balancing on one foot, when the weight of the body is on the fore part of the foot in walking, and still more so when carrying a pack on the shoulders. A good marching foot should therefore leave the foot free to adapt itself to altering conditions of balance and strain. The writer discusses the palliative and operative measures that may be employed in correcting these deformities.

3. A Case of Arteriovenous Aneurysm of the Sub-Clavian Artery and Vein Treated by Excision of the Sac and the Second and Third Parts of the Artery.—Comyns Berkerley and Victor Bonney report the case of a soldier who was wounded by a rifle bullet striking him just outside the axillary border of the right scapula near its inferior angle and emerging just above the middle of the right clavicle. The wound of entrance was healed and wound of exit practically healed, but underlying it in the subclavian triangle was a pulsating swelling about the size of a double walnut. There was a very marked thrill which could be felt and heard even as far as the bend of the elbow. The right arm was entirely paralyzed. A diagnosis of arteriovenous aneurysm of the third part of the subclavian artery and vein and injury to the brachial plexus was made. As the swelling in the neck was enlarging, and, if it continued to enlarge the difficulties of operating would become greater, it was decided that operation should be performed. The sac lay between the third part of the subclavian artery and vein, and communicated with both. The aperture into the vein was fortunately small and was situated about the point where the external jugular joined it. The sac wall was very thin. Its front part was formed by the deep cervical fascia; behind and above it adhered to the brachial plexus, while the first rib and clavicle had limited it below. There is only one other case in which an after history of arteriovenous aneurysm in this situation is available and this together with the successful result in the present instance justifies the decision to operate. The authors say that if they ever have to perform this operation again they will not replace the resected clavicle, for they think that if they had not done this suppuration would not have occurred. It would also they acknowledge, have been better not to have used silk for the main arterial ligatures. In all cases of military surgery where absolute asepsis could rarely be attained catgut of an absorption rate of not more than twenty days should be used for large arteries, a suture having this absorption rate being used so as to minimize the duration of a ligature sinus if by chance such a complication should happen to occur.

Calcium Sulphide an Antidote for Mercurial Poisoning.—B. Merrill Ricketts recently described a method devised by him to antidote mercury in the system after the swallowing of a lethal dose. For every grain of mercury ingested he gives one grain of calcium sulphide by the mouth and repeats it every two hours until five grains have been taken. If the case is already forty-eight hours old when treatment is begun he injects the drug into a vein—one grain in an ounce of water for each grain of mercury swallowed. Ricketts reported several cases of recovery, in one of which 80 grains of bichloride had been taken.—*American Journal of Clinical Medicine.*

Delayed Appearance of Tetanus.—Julliard, a Swiss surgeon connected with a base hospital in Lyons, states that preventive antitoxin may sometimes delay infection, while not mitigating its severity. He saw fatal cases which did not develop until two and three months after injury. In one of these, two months after aseptic healing of a wound of the os ilium, tetanus suddenly appeared and proved fatal in eight days. The author does not include here cases of delayed tetanus started up by secondary operations on wounds.—*Correspondenz-Blatt für Schweizer Aerzte.*

Book Reviews.

Back Injuries and Their Significance Under the Workmen's Compensation and Other Acts. By Archibald McKendrick, F.R.C.S.E., etc., Surgeon in Charge of Surgical X-ray Department, Royal Infirmary, Edinburgh. Blue muslin; pp. 174, with 14 illustrations. Price, $1.25 net. New York: William Wood & Co.; Edinburgh: E. & S. Livingstone, 1916.

McKendrick shows that he fully appreciates the situation, and also that he has a sense of humor, when he says in his preface, "Back injuries have a bad reputation. The workman looks upon them with apprehension, the insurance company with doubt, the medical examiner with suspicion, the lawyer with uncertainty, and the court with as open a mind as is possible under the circumstances." As he also says, the lawyers are puzzled by the conflicting and often contradictory reports of the surgeons; and this book is offered to the medical and legal professions as an honest attempt to throw some light into the existing darkness and to suggest some practical methods of testing the genuineness or otherwise of the complaints made. With this end in view the author discusses the anatomy of the spine, including its bones, joints, ligaments, and overlying fascia and musculature, then takes up the examination, history, and numerous other matters, tests, etc., which should be carefully considered in order to arrive at a correct diagnosis and separate the true from the "fake" cases.

This book was written with the laws of the British Isles in mind; but that interferes but little, if at all, with its practical value, since the author is concerned with the medical and surgical rather than the legal aspects of the subject. Since the Workmen's Compensation Law in this State went into effect the apparent number of slight injuries has increased enormously, treatment being sought for injuries so trivial that they would have been disregarded formerly; and as real or feigned injuries of the back have always been a fruitful source of claims for financial balm, it is probable that the apparent number of these cases will likewise show an increase under present conditions. Hence McKendrick's book is most opportune; and as it is well written and covers the ground quite thoroughly, it should be of much service to those who have to do with these often perplexing cases.

Cerebrospinal Fever. By Thomas J. Horder, M.D., Assistant Physician, St. Bartholomew's Hospital; Major (Temp.) R.A.M.C., Serving with the British Expeditionary Force. With Seventeen Illustrations. Price, $1.25. London: Henry Frowde; Oxford University Press; Hodder & Stoughton; New York: Oxford University Press, American Branch, 1915.

This is one of the Oxford War Primers of Medicine and Surgery. It is a book of exceptional merit, presenting a complete survey of the latest knowledge of meningococcus meningitis and serving at the same time as a practical working manual for the benefit of those who are actually treating cases of this disease. The methods of bacteriological diagnosis and the technique of lumbar puncture are described in satisfying detail. The chapter on diagnosis is excellent. It discusses the subject of meningism, the diagnosis of meningitis from toxemia merely, the acute infective processes with toxemic symptoms simulating meningitis, the differential diagnosis of cerebrospinal fever from certain diseases of the central nervous system and the differential diagnosis from other forms of meningitis. Considerable value is attached to the old distinction originally attributed to Sir William Jenner, namely, that if headache and delirium synchronize, meningitis is probably present and not merely toxemia. The chapter on treatment is thoroughly up-to-date. Preference is given to the gravity method of introducing the curative serum into the subarachnoid space, a method probably first employed in the Mount Sinai Hospital in New York. The control of the serum administration by watching the blood-pressure as advocated by Sophian is also discussed. The treatment by means of soamin (sodium aminophenylarsenate) as recently reported on the basis of successful results obtained in South Africa is fully described. In summarizing the many good features of this book one must not fail to mention the discussion of the carrier problem in this disease, the question of the incidence of abortive cases, and the pathogenesis, all of which subjects have come to the forefront within recent years. The fact is emphasized that the exact habitat of the meningococcus in carriers is the upper part of the nasopharynx and the posterior nares, and there is described and illustrated a method, as advocated by Dopter, of obtaining material from the nasopharynx by means of a special swab. This is a method of examination of definite value in the case of suspected contacts.

Character and Temperament. By Joseph Jastrow, Professor of Psychology, University of Wisconsin. Price, $2.50 net. New York and London: D. Appleton and Company, 1915.

That such subtle attributes of human nature as character and temperament should be capable of close analysis speaks well for the progress of modern psychology. At any rate, it is no longer considered that those elusive traits that distinguish the so-called qualities of men are beyond the scrutiny of science. Professor Jastrow has attempted to gauge these qualities and the result is a valuable contribution to psychological literature in a volume of 596 pages. This delineates the "foundations of human differences" and the "traits upon which education builds, which the vocations select, and which society encourages." One might aptly describe this book as a treatise on human nature. Its subject-matter is subdivided into nine chapters under the following headings: The Scientific Approach, The Sensibilities, The Emotions and Conduct, The Higher Stages of Psychic Control, Temperament and Individual Differences, Abnormal Tendencies of Mind, The Psychology of Group-Traits, Character and the Environment, and The Qualities of Men. This book bears the stamp of rare scholarship and is written in a singularly clear and elegant style.

A Text-Book Upon the Pathogenic Bacteria and Protozoa for Students of Medicine and Physicians. By Joseph McFarland, M.D., Sc.D. Professor of Pathology and Bacteriology in the Medico-Chirugical College, Philadelphia; Pathologist to the Philadelphia General Hospital and to the Medico-Chirurgical Hospital, Philadelphia; Fellow of the College of Physicians of Philadelphia. Eighth edition. Price, cloth, $4.00 net. Philadelphia and London: W. B. Saunders Company, 1916.

McFarland's text book upon the pathogenic bacteria and protozoa is almost a household word among the members of the medical profession in this country, and is of course well known and esteemed by English speaking medical men everywhere. The present, the eighth edition, has been almost rewritten; so much so indeed that the type of the entire book has been reset. The work is remarkably full and has been brought thoroughly into line with all the most recent developments of the subjects dealt with. All relating to the matter in hand is discussed exhaustively but at the same time in language concise and clear. The volume provides a valuable book of reference for students and physicians. The book is well printed and the illustrations are excellent.

Changes in the Food Supply and Their Relation to Nutrition. By Lafayette B. Mendel, Professor of Physiological Chemistry in the Sheffield Scientific School of Yale University. Price, 50 cents. New Haven: Yale University Press. London: Humphrey Milford, Oxford University Press, 1916.

The changes of the food supply and their relation to nutrition have a very important bearing on the health of a community. Modern methods of preparing certain staple articles of diet have resulted in various phases of ill health. Highly milled bread, for instance, is less nutritious by far than the coarser varieties, while polished rice has been shown to be responsible for beriberi. Pellagra and scurvy again are what is known as deficiency diseases, due to the lack or absence of vitamines in the article of food on which the sufferers therefrom have subsisted. Professor Mendel in his able essay has presented some very valuable facts in a very interesting manner.

Breathe and Be Well. By William Lee Howard, M.D. Price, $1. New York: Edward J. Clode, 1916.

In this book, which is written for the instruction of the laity, the author gives some very practical advice on the most important and greatly neglected subject of correct breathing, and shows how intimately it is related to the preservation of health. He gives directions for a number of breathing exercises, which may be followed by those who are unable to take brisk physical exercise in the open air. For those who can and do walk at a rapid pace several miles a day the breathing will take care of itself.

Society Reports.

AMERICAN MEDICAL ASSOCIATION.

Sixty-seventh Annual Session, Held in Detroit, June 13, 14, 15 and 16, 1916.

(Special Report to the MEDICAL RECORD.)

(*Continued from page 1164, Vol. 89.*)

SECTION ON MEDICINE.

Wednesday, June 14—Second Day.

A Consideration of Types of Uremia.—Dr. NELLIS B. FOSTER of New York presented this paper. He said that a diagnosis of uremia could not be based on demonstrable organic changes, since the organic lesions disclosed at necropsy were inconstant. The clinical manifestations of uremia were found in association with advanced renal disease and hence, presumably, were due to a defect in renal function; but if the kidneys were removed entirely the course of events leading to death conformed but remotely to any type of uremic state. Clinically, several types of uremia had been differentiated, depending on the presence or absence of group symptoms; these types might be in some instances pure, not infrequently merging together. As nephritis presented various manifestations determined by the specific renal function most impaired, so uremia could be divided into several groups and the primary factor determined with a high degree of probability. There were, according to his present conception, three pure basic types of uremia. (1) Retention type, the urinary poisoning of Ascoli. This was a simple retention of urinary nitrogenous waste—urinary poisoning. (2) Cerebral edema type. This was due to defective water and salt metabolism, resulting in cerebral edema. (3) The toxic type, or epileptiform uremia. This was a toxemia resulting from an abnormal katabolism.

The Value of Recent Laboratory Tests in the Diagnosis and Treatment of Nephritis, with Special Reference to the Chemical Examination of the Blood.—Dr. ARTHUR F. CHASE and Dr. VICTOR C. MYERS of New York presented this paper, which was read by Dr. Chase. He said the chemical examination of the blood in nephritis was often of greater diagnostic and prognostic value than the chemical and microscopical examination of the urine, the blood pressure, phenosulphonephthelein test, etc. The case of excretion of the three most important nitrogenous waste products, creatinin, urea, and uric acid, appeared to fall in the order just named, probably owing to purely physical laws of concentration and solubility. Thus a lowered kidney activity should become evident first by the retention of uric acid, later by urea, and lastly by creatinin. A retention of uric acid alone should form an early diagnostic test; an appreciable retention of creatinin should constitute a grave prognostic sign, a view well supported by their own observations. As a gauge to the acidosis which occurred in many advanced cases, they had found Van Slyke's method of determining the CO_2 combining power of the blood of great value. Of the large number of methods used in the past few years to estimate the functional capacity of the kidney, they felt that the following were of practical use to the general practitioner: Phenosulphonephthalein test, the determination of the fixation of the specific gravity and of nocturnal polyuria and the estimation of the blood content of the uric acid, urea, creatinin, sugar and CO_2 combining power. These tests, they believed, were distinct contributions to medicine and had come to stay. The amount of nitrogen in the blood served as a most excellent guide in the giving of protein. The use of salt-free diet in cases of parenchymatous nephritis with edema and salt retention gave prompt results.

A Comparative Study of Tests for Renal Function.—Dr. HERMAN O. MOSENTHAL and Dr. D. SCLATER LEWIS of Baltimore presented this paper—a comparative study of the phenosulphonephthalein, non-protein nitrogen in the blood, blood urea, Ambard's coefficient of urea excretion, and the test meal for renal function tests had been carried out in a series of cases. A definite scale by which to judge the degree of impairment of renal activity was proposed. These observations indcated that in most instances the results obtained by the various tests tended to be of equal degree. In a certain number of individuals, however, they were not. This discrepancy was not interpreted as invalidating either one test or the other, but was regarded as evidence that they signalized a diminution of various phases of renal function which did not necessarily parallel one another. When it was well understood what part of renal function each of these and other renal functional tests tried out, a more intelligent study of diseases of the kidneys might be made than heretofore. In summarizing they stated the following: (1) A scale of impairment of renal function was proposed according to which the tests might be measured. Such a gradation called to the attention of the clinician the relative degree of involvement as shown by different procedures. Inasmuch as each of them had a significance apart from the others, comparison according to this method was an extremely valuable aid in the treatment and prognosis of diseases of the kidney. (2) The level of the non-protein and urea nitrogen of the blood must be estimated largely as the resultant of three factors—kidney efficiency, diet, and protein destruction. In judging of prognosis, when these substances were high in the blood of nephritics, due regard must be given as to whether their accumulation was brought about by retention alone or through retention coupled with protein destruction. The former offered a comparatively better prognosis than the latter. (3) The coefficient of Ambard was a better bethod of determining the ability of the kidney to excrete urea than the level of this substance in the blood. (4) The progress of renal disease was probably followed most minutely by means of the 'phthalein excretion and Ambard's coefficient, as these tests furnished figures in which even small variations were of significance. (5) The test meal for renal function gave the earliest indication of diminished kidney efficiency. It likewise reached the maximum degree of impairment before the others. (6) Each test for renal function covered only a limited range of the kidney's activities. It was, therefore, a mistake to speak of any test as measuring renal function as a whole. The aim should be to develop a proper interpretation of the old tests and easily applied new ones, in order to obtain a true guide in the treatment of diseases of the kidneys.

Elective Localization of Bacteria in Diseases of the Nervous System.—Dr. EDWARD C. ROSENOW of the Mayo Foundation, Rochester, Minn., briefly summarized the results of an experimental study of the possible etiological relation of localized foci of infection, especially in and about the teeth and tonsils, to diseases of the nervous system. A table thrown upon the screen gave a summary of the results obtained in animals; the figures indicated the percentage incidence of focal lesions in the various organs. Lesions of the spinal cord, usually patchy in character, were observed in 58 per cent. of 31 animals injected with the bacteria from the tonsils or infected teeth in three cases of multiple sclerosis. In one of these the lesions appeared to be due to a staphylococcus; in the other two, to a green-producing streptococcus. Markedly increased reflexes, ataxia, and paraplegia were noted during the life of some of the animals. None became paralyzed. The duration of the symptoms ranged from three to eight years. In two additional cases little evidence of focal infection was found and the cultures failed to produce lesions in the spinal cord. Lesions of the spinal cord were noted in 78 per cent. of 36 animals injected with the staphylococcus from the tonsil in a typical case of sporadic anterior poliomyelitis. Lesions of the meninges and spinal cord occurred in 50 per cent. and 66 per cent. of 21 animals injected with the bacteria as isolated from the pyorrheal pockets and tonsils in a case of transverse myelitis with paralysis of the lower extremities. Partial or complete paralysis, which began in the hind extremities, developed in many animals. The lesions of the cord consisted chiefly of hemorrhages both in the gray and white matter and of leucocytic infiltration of the meninges and surrounding blood vessels. Lesions in or about one or more of the posterior roots occurred in 83 per cent. of 18 animals following the injection of streptococci from cases of brachial, intercostal, and post-herpetic neuralgia. The occurrence of neuritis in 28 per cent. of these animals was noteworthy. This and the high incidence of lesions in the skin, 28 per cent. (chiefly herpes) occurred in animals injected with relatively large doses. As far as could be determined, this was the first experimental demonstration of the probable nature of this form of neuralgia. Lesions of the peripheral nerves occurred in 79 per cent. of the 19 animals injected with the pneumococcus obtained on two occasions from multiple neuritis. Lesions in or about the joints occurred in

48 per cent. of the 29 animals injected, in the myocardium in 28 per cent., and in the muscles in 93 per cent., following injection of the cultures from 12 cases of "myalgia."

Thoracic Disease—The Status of Surgical Therapy.— Dr. SAMUEL ROBINSON of Rochester, Minn., read this paper in which he said that the treatment of diseases of the lung, the pleura, and mediastinum was in a lamentably chaotic state. Several quesstions arose: "Was it not probably that more cooperation between the internist and the surgeon might result in better treatment of the patient? Was the surgeon operating on lesions which the practitioner might cure? Was the practitioner treating some cases unsuccessfully which the surgeon might cure?" Surgery of the pleura began only where non-operatipe treatment failed. The surgeon would be found useful and safe in the treatment of post-pneumonic abscesses; in chronic lung abscesses he was less successful, and would welcome the exclusion of this group of cases from the surgical field. He was watching with interest the efforts with vaccines, climatic influences, and hygiene, but grieved at the limited accomplishments in this direction. He believed that early compression therapy in chronic abscess cases would do great good. Bronchiectasis would seem to be a chronic incurable disease. The records were hopelessly void of successes without surgery and painfully attended with fatalities by operation. Artificial pneumothorax had been reported as curable but grave doubts were entertained as to the truth of this statement. The writer warned against permitting a surgeon to drain a case of bronchiectasis. It would do no good, possibly much harm. Emphysema was again a stumbling block. Surgery offered but one operation, namely, the removal of several costal cartilages on one or both sides. In a considerable proportion of cases it relieved distressing symptoms, but it did not cure. It might justly be contended that our methods of exploring the pleural cavity were inadequate. In the management of tuberculosis the practitioner must cease to look to the surgeon for help. The tuberculous patient was *a priori*, a poor surgical risk and the outlook for successful extirpation of tubérculous lung tissue was particlarly discouraging. Neither was the drainage of a tuberculous cavity a profitable surgical measure. Of all swellings on the chest wall there were at least two types that were curable, the so-called "cold abscesses" and operable tumors of the chest wall. If there were lateral bulgings suggesting mediastinal tumor, the growth seen upon the chest wall was inoperable. The removal of an early localized malignant tumor of the lung was surgically possible, but the internist could not be expected to diagnose these tumors at an early stage. It was to be hoped that within a few years more successful extirpation of esophageal carcinoma might be recorded.

Localized Bronchiectasis Involving the Upper Portions of the Lung, with Report of Five Cases. — Dr. THOMAS MCCRAE and Dr. ELMER H. FUNK of Philadelphia presented this paper, in which they reported five cases of bronchiectasis that came to autopsy within a period of five months and represented the only instances of bronchiectasis in 80 consecutive autopsies from the service of the Department for Diseases of the Chest of the Jefferson Medical College. They illustrated particularly some of the problems of diagnosis. The features of the marked general cases of bronchiectasis were usually such that a diagnosis could readily be made. The problem was a more difficult one in cases of local bronchiectasis. Of particular importance in making a diagnosis was a history of chronic cough for a long period with considerable expectoration without marked constitutional disturbance, especially if the sputum was fetid. The cough being paroxysmal and often induced by changes in position was also suggestive. The presence of blood in the sputum was present in all of these cases, but could not be considered as diagnostic since it occurred in tuberculosis. Dyspnea was common, especially on exertion, and was most marked in the cases with considerable fibrosis. The problem of these upper lobe cases of bronchiectasis was largely that of differentiation from tuberculosis. The first case reported was in a man who had been in several sanatoriums with an invariable diagnosis of tuberculosis. It served to emphasize the fact that when symptoms and signs pointed to advanced pulmonary tuberculosis and repeated sputum examinations did not show the tubercle bacilli, the condition was not tuberculosis.

Another point which might aid in diagnosis was the disproportion between the signs in the lungs and the constitutional symptoms. Radiographic studies should be made in every case in the hope that in the future this diagnostic aid might be developed. The treatment was largely palliative. The adoption of a semi-erect posture facilitated drainage of the apical cases. After intratracheal inflations the patient should be placed in the recumbent position. Autogenous vaccines might be tried, although their value was undetermined. The five cases reported had the following distribution: right upper lobe, one; the right upper and lower lobe, one; both upper lobes, three. Tuberculosis was associated in four cases, three of which were bilateral. Syphilis was apparently excluded as an etiological factor. There was marked evidence of pulmonary fibrosis in the bronchiestatic areas. The error of taking bronchietasis for tuberculosis might be avoided by careful sputum examination.

Splenectomy in Pernicious Anemia—Studies on Bone-Marrow Stimulation. — Drs. ROGER I. LEE, GEORGE R. MINOT, and BETH VINCENT presented this study from the Medical Service of the Massachusetts Hospital. They stated that in the study of the diseases of the blood, and particularly of the effects of therapeutic procedures in such diseases, it was necessary that one should be able to estimate by reliable criteria any alteration of the relative rate and degree of destruction and regeneration, at least of the formed constituents of the blood. Such information was particularly desirable in pernicious anemia. The methods for studying the processes of destruction and regeneration were few. Fifteen cases of pernicious anemia were studied with reference to the effect of splenectomy on the blood forming organs with a view of determining, if possible, the value of this procedure in altering the activity of the bone marrow. An analysis of the end results in these cases certainly failed to show any permanent results from this procedure. The ultimate progress of the disease was not changed by the operation. There was in eight out of thirteen cases a considerable temporary improvement in two months which persisted in some cases until six months. The study of the condition of the blood in these cases led to the conclusion that one found stimulation of the bone marrow in pernicious anemia frequently occurring spontaneously. One might find stimulation of the bone marrow usually associated with improvement after splenectomy. Splenectomy seemed to result in the greatest stimulation of the bone marrow of any known therapeutic measure. It acted on the whole bone marrow and not only on the portion that formed the red cells. While more constant stimulating effects occurred after splenectomy, yet they could roughly parallel any given case of bone marrow stimulation after splenectomy with a case of bone marrow stimulation that occurred either spontaneously or after transfusion. It was evident that from splenectomy one could obtain stimulation but once. Transfusion, while perhaps of less constant and less active effect had the advantage that it was relatively simple, and it could be repeated a number of times. Transfusion did not modify the destructive agencies at work in pernicious anemia.

Late Results of Splenectomy in Pernicious Anemia.— Dr. EDWARD B. KRUMBHAAR of Philadelphia presented this paper which consisted in a statistical and critical review of the late results of splenectomy. He concluded that of the 153 cases studied, 19.6 per cent. died within six months; a distinct improvement in the clinical condition and in the blood picture occurred in 64.7 per cent., and there was no improvement in 15.6 per cent. The high postoperative mortality might be due to the poor choice of cases in the early series. A much greater proportion of the later cases had survived. Of the individuals, nearly two-thirds of the total number, that showed improvement shortly after operation, a large number had failed to maintain this improvement, or had since died in a relapse or from intercurrent disease. A few had continued in good condition during the period of observation, over two years. In no case could it been said that a cure had been effected, and the blood of these individuals continued to show many of the characteristic signs of pernicious anemia. On account of the improvement that followed splenectomy, it would appear that it was not only a justifiable, but in many cases an advisable procedure. The best results were obtained if the operation was preceded by one or more transfusions. Those cases that relapsed after operation might still be greatly helped by transfusion. The most favorable results might be expected in individuals who had not passed the fifth decade, in

whom the disease had not progressed for more than a year, and who had a relatively good blood picture. Individuals with enlarged spleens had done better than those in whom the spleen was small or normal in size.

Pernicious Anemia Treated by Splenectomy and Systematic Often-Repeated Transfusion of Blood—Transfusion in Benzol Poisoning. — Dr. Roy D. McClure of Baltimore read this paper. He said that there were many reasons why blood transfusions had not been of more value in pernicious anemia. Chief among these was the lack of systematic treatment. Usually about as much good was accomplished by a single transfusion as by a single inunction of mercury in syphilis. Discredit had also been incurred by using blood which had not stood the proper tests. The writer said that their attention was first drawn to the great value of repeated transfusions in 1914 in the treatment of benzol poisoning. The symptoms in this form of poisoning were a severe purpura hemorrhagica with a severe anemia of the aplastic type. Several transfusions were performed among these cases but there was only temporary improvement, and the procedure was regarded as of little value. In one instance, however, the family of the donor noticed the enormous immediate value of each transfusion and insisted that the treatment be continued. They produced the donors so that suitable blood was always supplied. Much to the surprise of all this patient soon ceased to require transfusions and made a complete recovery. This led to the conclusion that perhaps carefully planned transfusions, persistently used to prevent the anemia and its results, might be of benefit in pernicious anemia. Repeated systematic transfusions had been carried out only during the past year. The result, however, had been so encouraging that they felt that the life of a patient with pernicious anemia might be indefinitely prolonged if the spleen was removed as soon as the patient was in a condition to stand the operation. Transfusion should be performed until the hemoglobin was as high as 90 per cent. or more, and this should never be allowed to fall below 75 per cent.

Premature Ventricular Systoles and Their Clinical Significance.—Dr. John E. Griewe of Cincinnati presented this paper, which was illustrated by a number of polygraphic and electrocardiographic tracings. He said he wished to demonstrate the first principles in the recognition and treatment of this form of heart irregularity. While it was desirable from the standpoint of the clinician that graphic tracings should be made when practicable; nevertheless such abnormalities in the heart action could be distinguished by careful palpation of the pulse and auscultation of the heart sounds. In the great majority of instances premature ventricular systole was a functional disturbance. The real seat of the trouble was usually extrinsic to the heart. In the majority of cases auscultation of the heart would prevent errors in diagnosis since these premature contractions of the lower chamber of the heart usually gave rise to a very characteristic sequence of heart sounds. Cases showing premature ventricular systoles and no other sign of organic disease of the heart or kidneys should not be considered a bad life insurance risk. In a certain number of cases digitalis seemed to have a good influence. However, in a general way the immediate use of digitalis in premature ventricular systoles should not be looked upon as good practice. The prognosis should be based not on premature ventricular systoles but rather upon the underlying cause.

The Significance of Pulse Form. — Dr. Albion W. Hewlett of Ann Arbor read this paper. He called attention to two fundamental types of pulse form, the sustained and the collapsing. The latter might be produced by nitroglycerine and occurred frequently in fevers and less frequently in other conditions. Low blood pressure did not necessarily produce this type of pulse. The writer discussed the relative importance of the heart and blood vessels in its production.

The Relation of Changes in the Form of the Electrocardiogram to Functional Derangements of the Heart Muscle.—Dr. G. Canby Robinson of St. Louis presented this communication. He stated that the electrocardiogram clearly revealed disturbances of the cardiac mechanism, but it had not yielded many facts which might be taken as a measure of the functional capacity of the heart. The object of this paper was to point out certain abnormalities occurring in electrocardiographic curves which apparently accompanied functional deficiency of the ventricles. This was done with the hope that the electrocardiographic method might sometimes prove of value in determining changes in the functional capacity of the ventricular musculature. The abnormalities in the series of cases reported consisted in changes in the initial portion of the complexes, the Q—R—S group, and different from those yielded by contractions caused by the ectopic stimuli and from those changes which occurred with bundle branch block. These abnormalities were apparently dependent upon derangement of the intraventricular conduction which prevented the passage of the excitation wave either along the usual paths or at the usual rates throughout the ventricles. The normal spread of the impulse was hindered because the impulse reached the ventricles before the conducting system had recovered from the preceding contraction, and the records indicated in some cases that this derangement disappeared with prolonged ventricular rest. These observations were taken as evidence for the belief that in cases in which the ventricular complexes constantly showed certain abnormal forms there were functional changes in the heart which prevented the normal recovery of intraventricular conduction during diastole. It was shown that changes in form of the ventricular portion of the electrocardiogram might occur synchronously with functional changes in the heart, and evidence was offered for the belief that certain abnormalities in the form of the electrocardiogram indicated functional derangement of the ventricles.

Some Factors in the Production of Cardiac Dyspnea. —Francis W. Peabody of Boston read this paper in which he stated that a full realization of the significance of dyspnea, and a properly adapted therapy, could only be the outcome of a much more complete understanding of the pathological physiology underlying it than was possessed at present. Dyspnea implied an element of discomfort or of difficulty in breathing, which might depend on an increase in the rate or in the depth of respiration, but usually it was associated with an increase of both, and depended fundamentally on a hyperpnea or increase of the total amount of air breathed in a given unit of time. It might therefore be said that in patients with heart disease a decrease in the vital capacity of the lungs was an important and practically constant feature in the production of dyspnea. Associated with this and apparently depending on it, there was usually a hyperpnea in the more severe cases. In many severe cases further causes of dyspnea might be the presence of acidosis, and to a less extent, an increase of body metabolism. An accurate index of the degree to which the depth of respiration was limited might be had by the measurement of the vital capacity of the lungs. This was regularly below normal in cardiac patients who complained of dyspnea. In a large series of cases in all staegs of cardiac disease the decrease in the vital capacity has been found to run almost constantly parallel to the degree of physical disability.

Roentgenocardiograms — Polygraphic Strip Tracings of Heart Chambers by the Roentgen Ray. — Dr. Augustus W. Crane of Kalamazoo, Mich., presented this communication. He stated that Roentgen-rays passing through multiple slits would record simultaneously on a moving film the pulsations of several chambers of the heart. Tracings might be taken simultaneously from the aorta and pulmonary artery. The interpretation of such tracings was not obscured by the transmission of the impulses through the body tissues or by instrumental inertia and adjustments. Roentgenograms should be compared with electrocardiograms and sphygmocardiographic tracings.

Contribution to the Physiology of the Stomach: the Newer Interpretation of the Gastric Pain in Chronic Ulcer. —Drs. Harry Ginsburg, Isador Tumpowsky and Walter W. Hamburger of Chicago presented this contribution which was read by Dr. Tumpowsky. The writers reviewed current theories as to the hunger pain in peptic ulcer. They stated that there was a significant similarity between the condition of the stomach in hunger and in ulcer. The difference appeared to be largely a matter of degree of sensitivity caused by hyperacidity and hyperesthesia. Ten cases under the care of one of the writers at the Cook County and Michel Reese Hospitals diagnosed clinically as peptic ulcer were examined. The findings of strong contractions of the stomach accompanying the pain of gastric ulcer seemed to confirm the idea that the pain was due to tension. It was shown that the marked hunger contractions caused pain in a hyperirritable condition of the stomach by increasing intragastric pressure. The conception that gastric pain was due to tension would explain

many obscure conditions simulating gastric ulcer, such as achilia gastrica, chronic appendicitis, and gall-bladder disease. Hyperacidity alone might be a factor by reflexly causing hypertonous, hyperperistalsis, and pylorospasm, allowing greater tension to be produced. The subjective relief of pain by alkalies did not necessarily prove that acid was the cause of pain but might be interpreted on the basis that alkalis prevented the development of pain producing hypertonus by neutralizing the causative factor of such hypertonus, namely acid. Pituitrin stimulated contractions as was to be expected from its property of stimulating smooth muscle. Amylnitrite in the case reported abolished the contractions, probably by stimulating the inhibitory nerves or by lessening the reflex excitability. From the results obtained hydrochloric acid, from the strength that it might occur in the stomach, about 0.5 per cent., caused no appreciable effect. The authors stated that they did not feel justified in drawing final conclusions regarding the effect of acidity until more cases were studied whose emptying time and condition of the pylorus was more thoroughly observed.

Carbohydrate Restriction in the Medical Treatment of Gastric Hyperacidity and Ulcer.—Dr. Willard J. Stone of Toledo, Ohio, presented this paper in which he stated that it was safe to say that in the present state of our information, ulceration of the stomach or duodenum rarely occurred without long standing hyperacidity. Moreover the medical treatment and cure depended to a large degree upon neutralization of the acid secretions by the administration of appropriate food and sufficient alkali. It seemed that in the type of carbohydrate digestion, manifested by breads and cereals, there existed a slightly lower hydrochloric acidity but a more protracted secretion. Since there was no provision in the stomach for carbohydrate digestion it had seemed plausible, in this day of excessive sugar consumption, that this common dietetic fault might be responsible for the altered gastric secretion found in a large majority of patients suffering with hyperacidity, pyloric spasm, and ulcer. The point to be made was that the excess consumption of carbohydrates under normal digestive conditions was a different matter than excessive consumption when hyperchlorhydria was present. In patients with pyloric spasm or ulcer the excess was required to remain in the stomach during the process of protein digestion of the other constituents of a mixed meal, with the result that bacterial fermentation followed and the symptoms of amylaceous dyspepsia become evident. Their distress appeared to be due primarily not to the hydrochloric acid content of the stomach but to the bacterial elaboration of organic acids from carbohydrate fermentation. Later in the process of gastric digestion, usually after one hour, hypersecretion of hydrochloric acid occurred as a result of the stimulating effect of such organic acids as butyric, lactic, acetic, and proprionic. The Skaller meal had much to commend it. It consisted of five grams of Liebig's extract in 200 c.c. of water. It was more palatable and gave a truer picture of gastric secretion than the Ewald meal. Patients with hyperacidity, delayed motility, and ulcer did better when their intake of carbohydrate food was lessened. The writer said he was also convinced that restriction generally to those articles of food which containd more than 20 per cent., such as bread and potato, together with sufficient alkali to limit the secretion of hyperchloric acid had given better results than hitherto obtained. A general diet list was presented which the writer had found useful. In addition the patient was requested to take one glass of milk between meals and at bedtime. After each meal and after each glass of milk, a powder consisting of heavy magnesium oxide, soda bicarbonate, and bismuth subcarbonate was to be taken in from one-half to one teaspoonful doses in one-third glass of water. If evidences of hypersecretion were present the powder was given every two hours.

Syphilis as a Probable Factor in Vague Stomach Disorders.—Dr. Cabot Lull of Birmingham, Ala., read this paper. He said that nothwithstanding modern methods for thorough diagnosis of stomach conditions there still was too large a class of so-called "functional diseases" of the stomach which in reality were made up largely of sufferers from visceroptosis, pyogenic infections, early myocardial or valvular disease, hyperthyroidism, latent tuberculosis, and syphilis. There was a rapidly growing literature of organic syphilis of the stomach, diagnoses now being based on positive clinical *x*-ray and selological findings in spite of the contention of pathologists that the disease was rarely demonstrable in tissue examinations after operation or post mortem. Since Warthin found spirochetes in cardiac muscle, as well as in other organs which showed no lesion, which according to the older knowledge would be classed as syphilitic, one might accept his theory for the period of latency in persons who though free from symptoms for decades showed abundant organisms in their tissues. he assumed that a symbiotic relation existed between the organisms and the body cells. This view of latency in symbiosis would explain more satisfactorily such phenomena as the late parasyphilitic manifestations and the negative complement fixation test which became positive after provocative doses of antiluetic remedies. Several illustrative cases were cited and, in conclusion, the essayist expressed the opinion that the recognition by laymen and physicians of the widespread prevalence of syphilis, often of mild type and non-venereal in origin, with a more definite and satisfactory interpretation of the Wassermann reaction would lead to the relief of many cases of functional stomach disorder now neglected.

Syphilis in the Southern Negro.—Dr. H. L. McNeil of Galveston, Tex., presented this communication, in which he stated that it was the belief of the majority of physicians working among negroes in the South that the greater percentage of them were syphilitic. On the other hand it was the belief of physicians working among the better class of negroes, especially in the North, that such an estimate was not correct. Most of these opinions were based solely upon clinical observations and not upon scientific investigation. The work here reported was carried out on the negroes of the city of Galveston, the majority being of the laboring classes. The Wassermann and the luetin tests had been employed. The series consisted of some 1200 adult negroes, in 600 of whom both the Wassermann and the luetin reactions could be successfully followed, while in the remaining 600 only the Wassermann tests could be obtained. Of these 1200 negroes, 34 per cent. gave positive Wassermann reactions. Of the 600 negroes upon whom both the Wassermann and the luetin tests were done, 35 per cent. gave definitely positive Wassermanns, and 18 per cent. gave positive luetins, while the total percentage giving positive reactions to one or both of these tests was 42 per cent. Such statistics were of comparatively little value in arriving at a true idea of the prevalence of syphilis among a race of people, for it was a well known fact that the percentage of syphilis among patients applying for treatment to clinics was always much higher than among the healthy working classes. In order to determine the actual prevalence of syphilitic infection among the healthy working negro, they had made a special study of some 200 such cases. Among these cases were included all negroes admitted to the surgical wards of the hospital suffering from accidental injuries, and all were ruled out who were otherwise diseased. Of these apparently normal cases, 24 per cent. gave positive Wassermann reactions, 12 per cent. gave positive luetin reactions, and 28 per cent. gave positive reactions to either the Wassermann or the luetin tests. They had also made observations to determine what percentage of syphilis might be hereditary and what acquired. It seemed that the majority of cases of syphilis among the negroes were of the acquired type. Tests were made on patients having different diseases, and these seemed to show that certain diseases seemed to be directly connected with previous syphilitic infection, as shown by the extremely high incidence of positive reactions. In other diseases moreover, syphilis, although apparently not being the direct. or at least the sole cause of the disease, would seem to be connected with its occurrence in some way, chief among these being the characteristic form of acute or sub-acute diffuse nephritis, which was one of the most common causes of death among negroes. The occurrence of syphilis among whites of the same social class as the negroes would seem to be about the same as among negroes. In the better class of whites the occurrence was much less, while in the best classes, young and healthy medical students, it was almost *nil*. Syphilis was undoubtedly one of the chief causes of death and disease among negroes, ranking as high or higher than tuberculosis, Bright's disease, and pellagra which were the three other chief causes of death or disability among that race in this community.

SECTION ON SURGERY.

Wednesday, June 14—Second Day

Some Technical Features of Spinal Surgery, with Re-

port of Results in 150 Spinal Operations (Lantern Demonstration).—Dr. C. A. ELSBERG of New York read this paper and illustrated it with lantern slides and moving-pictures. Of the methods of approach to the spinal cord; namely, hemilaminectomy and complete laminectomy, the latter was the simpler and more reliable. He removed the spinous processes with forceps and resected the vertebræ so as to leave a tunnel 1 cm. across. For spinal decompression, he made the opening 1½-3 cm. wide. The results of spinal decompression were as good as cranial. He recommended the removal of the tips of the adjoining spines. The normal color of the spinal cord was creamy white. In meningo-myelitis, the color was pink and the veins were congested. Congested veins sometimes pointed to obstruction higher up. In multiple sclerosis, the cord was thin and pale and the vessels small. When tumors were situated under the intraspinal portions of the nerves it was better to sever the nerves and lift out the tumors than to drag them out while the nerves remained intact. Adhessions occasionally demanded relief. Large tumors were soft and less injurious to the cord than the small hard ones. He had performed 150 laminectomies with 15 deaths. Of the 15, 10 were about to die at any event. He used fine silk to suture the dura and interrupted sutures for the fascia and skin.

Dr. SACHS of St. Louis said that Dr. Elsberg had passed over several of his contributions to spinal surgery. The approach to the anterior surface of the cord was difficult. By severing the ligamentum denticulatum and pulling on the stump, the cord could be displaced to expose it. The differentiation of the circulatory disturbances was of diagnostic value in determining the nature of the cord lesion. Opening of the dura was sufficient to produce distention of the cord veins. He emphasized the importance of securing a dry field before opening the dura. He was accustomed to use hot cotton to absorb the blood; he had never tried the suction apparatus recommended by Elsberg. He made a subperiosteal section instead of cutting the muscles and protected the sides of the wound with gauze. He endorsed the resection of the spines. The least possible traumatization to the nervous system was desirable. There was a danger, he thought, in moving-pictures giving the impression of rough handling.

Dr. ELSBERG said, in reply, that he cut the muscles against the spines without cutting into them. Although the spinal nerves distended when the cord was exposed, the distension never equaled that of obstruction or of meningo-myelitis.

Surgery of the Brachial Plexus.—Dr. ARTHUR A. LAW of Minneapolis read this paper. He said there were many such injuries coming out of the war. He described the mechanisms that were responsible for them. They were not only due to direct but, as Horsley has shown, to indirect violence. The successful surgery of spinal nerves demanded a knowledge of the regeneration of the nerves. It had been shown that nerves grow across a gap. Wrapping the interval with fascia or fat prevented throttling with connective tissue. Regeneration occurred if the ganglia were intact. In avulsion, nerves were torn and frayed, there were endoneural hemorrhage and fibrous tissue replacement. There were 21 cases of avulsion of the brachial plexus up to 1911, as proven by operation. Hartwell and Murphy reported two cases. None of the avulsions occurring in adult age showed complete recovery after operation. He considered the improvement sufficient to justify operative intervention, however. He reported two personal cases in one of which he had repaired a three-inch loss in the musculospiral nerve.

Dr. DEAN D. LEWIS of Chicago said that 36 per cent. of nerve sutures were satisfactory. The results of secondary were about the same as primary nerve suture. He held that the neuro-tropism did not exist in the axis-cylinders for if it did one should get regeneration from a severed cord. There was 5/6 proliferation from the central and 1/6 from the peripheral end. The auto-transplant was the best bridge. Law was to be congratulated upon the results he obtained in these two cases.

Dr. LAW, in conclusion, spoke briefly upon the subject of neurotropism from an experimental point of view.

Free Transplantation of the Omentum Subcutaneously and Within the Abdomen.—Dr. CARL B. DAVIS of Chicago read this paper. Omental grafts did well where transplanted. There was considerable adhesion formation about the raw edges which indicated the turning in of the cut edges. He had lacerated the liver and used omentum as a plug and as a flap over the lacerated portion with the result of hemostasis. He illustrated the results of omental grafts to stomach, intestine, liver, and spleen by lantern slides.

Dr. ALFRED STRAUSS of Chicago said that the advantage in leaving the omental flap intact was that it was kept alive. He drew attention to his method of pyloric occlusion with fascial transplant. He had resected stomachs of 26 dogs and placed fascia in the gaps. In both series he kept the fascial grafts alive with omentum layed over them.

Dr. JOHN S. DAVIS of Baltimore said that Stone of Boston had scraped intestine, applied omentum over the scraped portion, and observed adhesions only at the cut edges of the grafts. Senn had used omentum freely in 1888! The use of omental grafts prevented adhesions and hemorrhage and reinforced suture lines.

Dr. A. T. MANN of Minneapolis had removed a large overian cyst and left an extensive raw surface which developed a mass of adhesions for which he had to reoperate within one year. He transplanted the entire omentum over the raw area. Within a year from the first operation, he had to operate upon the same patient again for ovarian cyst in the remaining ovary and found at this time the intestines free and the fat gone. He concluded it was feasible to transplant the omentum.

Operative Treatment for Threatened Gangrene of the Foot, with Special Reference to Reversal of the Circulation (Lantern Demonstration).—Dr. JOHN S. HORSLEY of Richmond, Va., read this paper. The essayist recognized four forms of circulatory disturbance: the arteriosclerosis of wear-and-tear of old age, of syphilis, etc.; intermittent claudication (arteriosclerosis with spasm of the vessels), Renaud's disease (with spasms on the arterial or venous or both sides of the capillaries), and thromboangiitis obliterans (the German endarteritis). Berger had shown occlusion of toxic origin. Thromboangiitis occurs in young people between 20 and 40 and usually in Russian Poles. The treatment is local and general. Kocher used Ringer's solution; so did Willy Meyer. Five hundred c.c. of the solution were given repeatedly. Carrel and Guthrie performed an arteriovenous anastomosis and observed the circulation always reversed (during a three-hour observation). The author thought the fallacy of Carrel's observation arose from his dependence upon the color of the blood for the veins often carried red blood (as after conditions of arterial constriction). He believed the blood traveled down the large veins past the valves into the small valves where after its resistance is spent, the blood is arrested by one of the small venous valves and forced to return by a collateral circulation. He showed slides representing the circulations in birds and dogs following anastomoses. He believed tying the femoral offered as good results. In either case, the clinical improvement was not entirely successful.

Dr. DEWITT STETTEN of New York said that arteriovenous anastomosis gave improvement by shunting the blood back through the venous trunks but that it was difficult to perform; the anastomosis might not remain open, and the operation should be abandoned. Ligation secured whatever results were obtainable by anastomosis. His treatment consisted in hygiene, posture, rest, moist dressings, and alternate hot and cold. He believed that he causative factor was similar in nature to that in hemophilia, an abnormality of the blood, a hereditary character.

Dr. CHARLES GOODMAN of New York replied in favor of arteriovenous anastomosis. He said that they had waited 200 years for saline solution although formerly plain salt solution was used. Still the present solution was not identical with blood. It was not known how much blood reached the periphery after anastomosis but there was evidence of relief of symptoms and the impending gangrene was averted. Bernheim had collected 56 cases, 15 being successful. He reported 6 satisfactory out of 14. Others were reported since. The experiments offered did not contraindicate the operation of anastomosis. Endarteritis and thromboangiitis were of infective origin. He had several instances of 3 plus and 4 plus Wassermann reactions.

Dr. N. GINSBURG of Philadelphia had seen many cases. They had come from Jewish people. There was no operation indicated except in thromboangiitis obliterans. He believed femoral vein ligation and crossed anastomosis palliative, only. Both procedures engorged the extremities. He had noticed a preponderance of the disease in male Russian Jews, many of whom were cigarette smokers. The origin was probably toxic.

Dr. Carl Beck of Chicago said that Horsley's inference that Carrel depended upon the color of the blood in tracing the course of the blood after anastomosis was incorrect. He had worked with Carrel and knew that he had drawn his conclusions from the position of the vessels. He reported a case of his own with a prompt filling of the vein. Bismuth injections were in his opinion illusive.

Dr. La Place of Philadelphia said that thromboangiitis affected certain people only. Specific treatment availed in some of these cases. After amputation, a black line formed about the end of the stump. It was wrong to sew up the wound. There was something defective in the healing process. He found bathing the end of the stump with serum beneficial in every case of his.

Dr. J. F. Corbett of Minneapolis said that collateral circulation sometimes accomplished much and deserved some credit. The rate of flow in a normal dog differed from that in senile gangrene of man. Animal experimentation in this particular condition was of little value. Sugar and urea increased as did the viscosity of the blood in these cases. Viscosity increased in other conditions as well. He could not offer anything operative but amputation.

Dr. Horsley, in conclusion, replied that he had not proposed any operation for gangrene. Ligation helped in some instances. There might be a metabolic toxin in the condition. He thought gelatin injection and animal study reliable.

Stab Wounds of the Chest Involving the Diaphragm with Diaphragmatic Hernia.—Dr. Charles C. Green of Houston, Tex., read this paper. Evisceration through the diaphragm occurred most often on the left side, for the liver acted as a barrier on the right. One report of 64 cases gave 45 protrusions of the outer wounds; one of 13.5 herniæ; one of 16, 9 protrusions at wound; and in 190 instances there were 98 or 52 per cent. eviscerations. He enumerated personal case-reports. Diagnosis was often not made until obstructive symptoms intervened. The mortality in the complicated cases was 64 per cent.; that in the uncomplicated was 20 per cent. In doubt, to save life, exploratory thoracotomy should be done.

Dr. James E. Moore of Minneapolis said that this paper was up to the minute and that the advances in the next decade in surgery would be in thoracic work. With intratracheal insufflation, the thorax could be opened with impunity. After a stab wound of the chest, the thorax should be opened; it would be perfectly safe, and might save life.

Dr. Charles C. Green of Houston, Tex., said that the main danger was collapse of the lung which caused shock. But pneumothorax had already developed in some instances. As soon as the ruptured edges of the diaphragm could be seized and held together, there was no danger.

Thursday, June 15—Third Day.

This was a joint meeting with the Section on Medicine.

The Immediate Effects of Splenectomy in Pernicious Anemia.—Dr. Heinert of Boston read this paper for Dr. Roger I. Lee of Boston. There was a typical blood count in 15 cases of pernicious anemia. After splenectomy, 4 improved in red cell count, 3 were unchanged. Ten were living after 10 months. Of these five had relapses and five did not. Three died one year postoperative. The leucocytes varied from 2,000 to 5,000, subsided in a few days, and tended to increase. The platelets were low after operation for 3 to 7 days and increased after, which increase often persisted. (9,000). Many showed an increase, especially in the large platelets. Platelets were known to be increased in thrombosis and in this series three were thrombosed. Howell-Jollie bodies occurred in 2-10 per cent. of the red cells after splenectomy. These bodies were supposed to be related to changes in the bone marrow. The blasts fluctuated. Of the red cells 0.8 per cent. were pigmented. A high percentage of these indicated activity of the bone marrow. There was a rise in the reticulated red cells after operation. The temperature improved and was associated with activity of the bone marrow and improvement in the blood picture. The cause of stimulation of the bone marrow was not known. Operation did not alter the essential course of the disease. Evidently, such a stimulation can be obtained but once. Transfusion did not modify the destructive agents at work.

Late Results of Splenectomy in Pernicious Anemia.—Dr. E. B. Krumbhaar of Philadelphia read this paper. In 1913 Eppinger and von Decastello independently applied splenectomy to the treatment of pernicious anemia. The prompt improvement in the early cases led to a widespread trial. Of 117 cases reported, 34 had died (mortality 29 per cent.). Of these, 18 died within six weeks of the time of operation (15.2 per cent.). In most of the other 99 cases there was a marked improvement for a varying length of time and in some during the whole period of observation. Of 19 patients, alive at the end of a year, 6 had died subsequently, 8 were still improved, and 5 were the same as before operation. Eighty-four cases, studied in respect to duration of the disease before operation, showed 11 improved and 4 deaths in 15 of six months' duration; 18 improved and 7 deaths in twenty-five one-half to one year cases; 25 improved and 10 deaths in 32 one to two-year cases; and 6 improved and 8 deaths in 13 two-year cases. The earlier cases gave the best results. In respect to the size of the spleens, of 19 cases of large organs, 1 died and 18 were improved; in 23 normal or diminished spleens, 9 died and 14 improved. The diagnosis of pernicious anemia was not perfect. The average duration of all cases was one and a half years. The most suitable for operation were the short duration cases with large spleens (or those with marked blood destruction showing increased unrobilin destruction). Contraindications were cases with symptoms of spinal cord disease, with no signs of blood destruction, or with aplastic bone marrow.

Splenectomy in Chronic Anemia, Exclusive of Pernicious Anemia, and in Chronic Icterus.—Dr. Joseph L. Miller of Chicago read this paper. The value of splenectomy in splenic anemia was unquestioned. Since this disease was improved, operation improved hemolytic jaundice and the cirrhosis of Hanot. All were characterized by chronic icterus, chronic anemia, or both, and splenomegaly. The stools were stained with bile. There was an hereditary tendency in icterus, and in splenic anemia. Anemia was not present in Hanot's Disease; this differentiated it from icterus. In hemolytic icterus, there was a disturbed resistance of the red cells; there were hemolytic crises. Splenic anemia was thought by many not to be a distinct entity; it was not a logical entity etiologically but might be so considered for therapeutic purposes. The anemia improved following operation. Banti's report covering the past ten years gave 44 per cent. mortality; since 1910, 19 per cent. The fatality at the Mayo clinic for eighteen cases was 11 per cent. Antisyphilitic treatment helped some but *x*-rays seemed of no avail. Splenomegaly occurred early in hemolytic icterus or it had not occurred at all. After splenectomy the hemolytic function (of the spleen) disappeared. Three or four cases of the cirrhosis of Hanot had been treated by removal of the spleen; it was impossible to foretell the efficacy of this treatment.

Splenectomy for Hemolytic Jaundice.—Dr. Charles H. Peck of New York read this paper. Splenectomy was beneficial in hemolytic jaundice. No bile appeared in the urine after operation. The symptoms of the congenital and familial types were the same. The author's case of congenital hemolytic jaundice was the first American case operated upon. The patient had jaundice at 20 which became intermittent from 20 to 30. She had a fragility of 70 which dropped to between 35 and 40 three years after operation. The leucocytes rose, then became normal in number. The spleen was moderate in size, its surface was roughened, it showed interstitial hemorrhage and follicles somewhat crowded out. The return to normal of the red cell fragility was especially noteworthy. The second case was of the acquired type. There was slight fragility before and no change after operation. The secondary anemia was moderate in amount. There were urobilin and urobilogen in the urine. The spleen weighed 800 grams. This case had been well since operation. The third case was of the congenital type and was operated upon by Dr. Warren. Jaundice disappeared and improvement followed after splenectomy.

Indications for Splenectomy in Pernicious Anemia and the Technique of the Operation.—Dr. Donald C. Balfour of Rochester, Minn., read this paper. Of four cases splenectomized for pernicious anemia, two improved. Three syphilitic spleens had been removed. The advocacy of splenectomy for pernicious anemia was stronger as the anemia approached other forms with recognizable indications for the removal of the spleen, as hemolytic jaundice. Pernicious anemia was in-

curable. There was, however, no better therapeutic remedy for the disease than splenectomy. The indications were (1) splenomegaly (which means overactivity, and palpability of the spleen. Thirty-seven cases weighed over 400 grams); (2) icteroid types; (3) activity of the disease (preferably the intermediate rather than the acute or terminal stages of the disease); and (4) duration of the disease (preferably short). In separating the spleen from the diaphragm, especially where adhesions were present and hemorrhage was liable, it was well to pack well up under the diaphragm with hot gauze. The spleen should be drawn toward the midline and its pedicle dissected back. The vessels were clamped and ligated. There was no recognizable advantage in tying, first, the artery to allow more blood to return to the body. In favor of splenectomy were the low operative mortality, the improvement, and the lack of superior therapeutic measures.

Pernicious Anemia Treated by Splenectomy and Often-Repeated Blood Transfusions. — Dr. RAY MCCLURE of Baltimore read this paper. The essayist said that blood might not mix, it might clump, hemolyze, or agglutinate. In the selection of a donor, a proper test required the elimination of such blood. It was the rule to allow one hour for the testing of each blood, and it was often necessary to try out eight to ten individuals before a proper donor could be decided upon. He reported one case in which syphilis was transmitted because the donor's history was relied upon instead of waiting for a Wassermann reaction. Benzol cases were treated by repeated transfusions; one with a hemoglobin of 20 was raised to 95. They had performed sixty-four transfusions in 17 cases. These were harmful in seven and helpful in the others. Those harmed suffered from the lack of good donors.

Dr. FRANK SMITHIES of Chicago said in the past three years they had performed multiple transfusions and splenectomies in 27 cases. The study brought out the toxic or infective nature of the ailment. There were foci of infection in the blood-making organs and in tonsils, teeth, throat, appendix, or elsewhere. There might be foci in the blood-destroying organs as Balfour had pointed out spirocheta in the spleen. Splenectomy was the less essential part of the treatment. Transfusions supplied antibodies and while these were being given possible foci of disease should be eradicated. They had had two operable deaths. It was their practice never to hurry. Ninety per cent. showed active or past appendicitis, gall-bladder disease, or perisplenitis. The average gain in the hemoglobin after operation was 43 per cent. and over 3,000,000 red cells. The improvement in the general condition equaled that in the blood, the longest case remaining better twenty-seven months.

Dr. BETH VINCENT of Boston said that the amount usually transfused was 600 c.c. The mortality in splenectomy should be low in pernicious anemia. The spleen should not be removed during a relapse. Certain forms did not improve after transfusions; others did not after operation. For relapses, transfusions were the best treatment. Both supplying new blood and the removal of the spleen were palliative measures which secured temporary and uncertain benefits.

Dr. H. Z. GRIFFIN of Rochester said that thirty-nine splenectomies gave a mortality of 7.6 per cent. There was no reason for high mortality. Three of the deaths were operative and four postoperative. One case lived three years. Twenty-seven survived. The longest time of good condition after operation was one year (two cases). They transfused to improve the patient's condition for operation and during relapses after operation. In thirty-three cases, examinations of the duodenal pigments showed high value before and low values after operations (in pernicious anemia). The mortality in splenic anemia was 15 per cent. Hemolytic jaundice and syphilis should be differentiated. The mortality in hemolytic jaundice was 10 per cent. There was no decided drop in fragility in any of these cases following operation. He was interested in the hemolytic jaundice cases with pernicious anemia blood counts.

Dr. W. S. THAYER of Baltimore said that the symposium was of great value. He had seen his first case three years ago, a case with cord changes that improved (although others reported none with cord changes improved). It was important to acquaint the patient with his chances under operation for pernicious anemia. The disease was ultimately fatal; the remissions were variable in length; in one, five years, terminating in death from another malady. In splenic anemia, operation was advisable. In hemolytic jaundice, the results of operation appeared to be beneficial. In the congenital type, the symptoms were not grave, life was endurable and he did not feel justified in recommending splenectomy. In the acquired form operation might be imperative. In splenic anemia, splenectomy might give good results. He had waited six months for one individual to improve and finally operated and transfused at the same time.

Dr. G. A. FRIEDMAN of New York said that he had seen the case at the Vanderbilt Clinic on whom Dr. Peck operated. She was more enteric than sick. She complained of dyspeptic symptoms. He advised sending such cases to the surgeon for operation.

Dr. S. J. MELTZER of New York said the rule was for the red cells to run in the middle of the blood streams. Forty years ago he had seen a case with the red cells at the periphery and thought they had been subjected to shock (which they might have received in passing through the spleen). In the last year Dr. Gates of the Rockefeller Institute had splenectomized dogs and had shown the effects of shaking upon them. He did not wish to claim or deny traumatic effects of the spleen in pernicious anemia. Splenic traumatism might explain the greater resistance of the red cells after splenectomy.

Dr. W. BREM of Los Angeles gave repeated transfusions. He believed by this means he could keep a patient alive indefinitely or pull him out of a hole. Blood-grouping for the selection of donors could now be accomplished in a few minutes. He had performed 179 transfusions after such tests without a reaction. He had given twelve without previous tests and without reactions. In four instances where the red cells were hemolyzed, severe anaphylactoid symptoms followed.

Dr. LEE of Boston said that the blood picture in pernicious anemia was the balance between blood-making and blood-destruction. He had studied splenectomy and transfusion from the standpoint of stimulation of the bone marrow. The quality of the reticulated red cells gave information as to the result of this stimulation. The benefits of transfusion were the furnishing of blood bulk and to bring about a remission through bone marrow stimulation. Other cases not treated showed the same changes.

Dr. KRUMBHAAR, in conclusion, said that much worse results followed splenectomy associated with a low hemoglobin (20 per cent.). There might be found a set of splenic cases that would give uniformly good results.

Dr. MILLER added that not every case of hemolytic jaundice should be subjected to operation. There had been three cases apparently cured as the result of *x*-rays.

Thursday, June 15—*Third Day.*

DR. F. T. MURPHY OF ST. LOUIS IN THE CHAIR.

Election of Officers.—Dr. W. S. Hagard of Nashville was appointed *Chairman*, Dr. A. A. Law of Minneapolis, *Vice-Chairman*, Dr. E. H. Pool of New York, *Secretary*, and Dr. D. Lewis of Chicago with Dr. J. T. Bottomley of Boston were chosen *Delegates to the House of Delegates* for the ensuing year.

Removal of the Right Colon—Indications and Technique.—Dr. CHARLES H. MAYO of Rochester read this paper. Years were required to standardize the diseases that warranted colectomy. Only those who were toxic from the intestinal contents and in whom there was a delay of three days or more were at present considered proper subjects. The removal of the right colon removed the absorbing surfaces of the colon and was less fatal than the removal of the whole large intestine. The lower ileum developed with the large colon or at least these two parts fell on the same side of the attachment of the vitelline duct. He described the physiology of the intestine and his technique of resection. He removed the terminal ileum with the right half of the colon and joined the terminal end of the ileum with the side of the end of the remaining transverse colon by means of a Murphy button. The extreme end of the colon or the portion protruding beyond the new iliocolic anastomosis was caught up in the closure of the parietal peritoneum and left accessible at the abdominal wound that it might serve as an outlet for gas from the colon after operation, if necessary. Tumors, granulomata, and colons of toxemic origin were resected in this way. Few of the cases had postoperative diarrhea. Appendicostomies might be done to allow escape of gas in operations upon the left colon. There were 262 resections of the left colon for malignancy and 54 per cent. living or 67 per cent. alive three

years after. The last twenty consecutive colectomies were performed without a fatality. There was a 13.5 per cent. mortality in ninety-six hemicolectomies and a 14 per cent. fatality in twenty-seven ilio-colostomies.

Some Results of Colectomy and Exclusion of the Colon in Cases of Chronic Arthritis.—Dr. JOHN T. BOTTOMLEY of Boston read this paper. Chronic infective arthritis was poorly treated by the profession. The intestinal stasis origin of the arthritis was an attractive theory. Ten of fourteen multiple, nontubercular cases were reported relieved by operation by Dr. Rea Smith. Anastomoses, colectomies, and other operations were performed. The toxic symptoms were reported relieved. There were increased joint action and improved bowel evacuation. In the author's cases the relief was temporary. One case remained cured three years after; another ten months (with diarrhea) later. Of thirty-one cases, twelve were cured. Of these twelve five were colectomies and seven iliosigmoidostomies. Colectomy in Lane's hands was more satisfactory than in ours because his experience was wider and his technique better. There was diarrhea in two cases. The joint cases that did not improve followed the natural course of the joint disease and were not aggravated by the operations. It was desirable to exclude infections of the sinuses, ureters, seminal vesicles, vagina, and other possible sources before turning to the intestinal tract. The neuromuscular apparatus of the bowel in intestinal stasis was at fault not the adventitious bands. Smith advised doing colectomy or iliosigmoidostomy. (Operations helped some and not others.) Persons to be operated upon for stasis should first understand the chances of a successful issue.

Dr. REA SMITH of Los Angeles said that Mayo's operation did away with a backing-up into the colon. In Lane's cases of short circuiting adhesions appeared in patches due to infection from his suture during anastomosis. There were less such adhesions after colectomies. Of fourteen cases there were two deaths and three perfectly well excepting for bony ankylosis (due to periarticular inflammation). These lived 18 months, 2 years 2 months, and 2 years, respectively, postoperative. Of the remaining nine, two were uninfluenced and seven were little better. None would go back to former condition. All were better generally, in respect to pain if not to joints. Drainage of the intestine seemed to influence the pain; less aspirin had to be taken for its relief after operation.

Dr. W. R. MAC AUSLAND of Boston said that in ten cases the routine measures failed. Intestinal symptoms and the chronic arthritis were not relieved. Upon relative relief was the only basis of comparing results. The joint cases should be taken before the advanced destructive stages. The time involved in these changes was 1 to 1½ years. Deformities should be prevented or corrected. Stasis was present in all.

Dr. J. M. LYNCH of New York said that the time had come when the iliocecal valve should be recognized as either muscle or valve. If a muscle, operation was of little value. If a valve, then operation was of some avail. Elliott supported by Bayliss, Starling and others, had shown that the arrangement was a muscle. Ten minims of adrenalin shut the valve tightly as a drum; later the same valve might relax into insufficiency. The relations of the internal secretions to the iliocecal sphincter were to be studied. He had performed twenty-eight colectomies (partial) and six cecosigmoidostomies. All the latter had been failures.

Dr. TUCKER of Cleveland asked upon what Mayo based his operability for his colon cases. Were the mechanical changes or the operative feasibility considered?

Dr. J. S. HORSLEY of Richmond, Va., said that Cannon showed that adrenalin caused dilatation of the gut by relaxation of the smooth musculature and did not understand why the valve should be contracted.

Dr. J. W. DRAPER of New York replied that the understanding was that adrenalin caused relaxation of the gut and contraction of the valve. It was an arrangement for estimating the functional disability of the valve. He reported one case of a woman in the terminal stage of polyarthritis who was unable to use her hands to write or handle her knife and fork who was able to turn over in bed in twenty-four hours after hemicolectomy. The rapidity of relief suggested a biochemical in place of or in addition to an infective arthritis.

Dr. JOHNSON of Memphis said that all agreed the area involved was the ilocecal region. It was due to a regurgitation of cecal contents into the ileum, the absorption of which caused a paralysis akin to that of lead-poisoning. The bands over the ileum and cecum denoted inflammation. Patients who developed splanchnoptosis had sick headaches and toxic vomiting in early life. The causes of the ptosis and of the toxic symptoms were the same. He had performed 11 colectomies, one to the sigmoid loop. The fixation of the end of the colon prevented sacculating or sagging. The omentum should be saved: it prevented some of the infection.

Dr. MAYO replied that cases hopelessly metastesized were not operated upon. Cases of parietal fixation were operable, as were all tumors of the colon.

Perforating Ulcers of the Stomach and of the Duodenum.—Dr. R. P. SULLIVAN of Brooklyn read this paper. He said the tenderness of ulcer was acute and easily elicited over the ulcer site. It was in the right iliac region in fifteen duodenal and in the epigastric region in five gastric ulcers. Vomiting was present and gave relief at first and suffering later. The vomitus depended upon the food and the site of the ulcer. Rigidity occurred early. He had relied chiefly upon the pain and rigidity. There was only one case without a preulcerous history. Eleven diagnoses of chronic ulcer had been made. Shock was present late in one case only. The temperature averaged 99.4 and the respirations 34. Appendix and gall-bladder disease should be differentiated if possible, though in either event operation was indicated. The average duration of symptoms before operation was six hours. His cases were fifteen duodenal and five gastric ulcers. Of the gastric, three were anterially placed, one at the lesser curvature, and one on the posterior wall. Gibson disapproved of gastroenterostomy for ulcer. Gastroenterostomy was added in each of ten cases in which the lesion was at the pylorus. He repaired the perforation and performed gastroenterostomy if seen within ten hours.

Dr. C. PECK of New York said that ulcers were acute with immediate leakage, chronic with no considerable leakage, and of the type that leaked a little from time to time. The leakage from an ulcer at the pylorus was slight; gastroenterostomy should be performed for such an ulcer at the first or at a subsequent operation. He had seen a reperforation one year after closing an ulcer. From 1910-1915 he had had thirty perforated ulcers, two-thirds duodenal and one-third gastric. Gastroenterostomies performed mostly in the latter cases, did not add to the operative mortality. Cases seen within the first 10-15 hours mostly survived.

Dr. BOTTOMLEY of Boston said that he did not agree with doing away with the drainage even in the early cases. He had seen turbid fluid in the abdomen in 1½ hours. Drainage increased the margin of safety and should be continued for 48 hours. Liberal diet should not be given after operation. The source of the infection causing the ulcer should be sought and eliminated if possible.

Dr. W. D. JOHNSON of New York said that a chemical peritonitis (which was not severe) preceded a bacterial peritonitis. Rigidity was marked. Absence of liver dullness was a late sign and should not be included.

Dr. SULLIVAN replied that drainage was a matter of opinion. The chemical peritonitis excluded the necessity for early drainage. Absence of liver dullness might be due to gas in the colon.

Plastic and Reconstructive Surgery.—Dr. J. S. DAVIS of Baltimore read this paper. Dr. Davis said that the need for reconstructive surgery had increased as a result of the war. Such surgery required special training in addition to a general surgical experience. Few cases were operated upon for cosmetic reasons, alone; many for economic reasons.

Dr. J. S. MARVEL of Atlantic City reported a case with a large fenestra of the anterior abdominal wall cured by skin-grafting.

Dr. J. S. STONE of Boston said much surgery was indicated in malformations and after trauma. Knowledge of the growth and of the repair of tissues was necessary.

Sarcoma of Intraabdominal Testicle.—Dr. W. W. GRANT of Denver read this paper. Sarcoma was most common in the undescended testicle. Ewing considered most testicular tumors primarily teratomata. He reported a case seen in 1913. He operated upon this case when first seen, administered Coley serum, and *x*-ray treatment; and removed the growth at a subsequent operation (1915).

Dr. W. B. COLEY of New York said that the essayist's success was due to successful treatment with the serum. He seldom injected directly into the tumor as

the author did. Of 64 cases of sarcoma of the testicle, twelve were undescended. He had operated upon fifty undescended testicles and had not seen one sarcoma among them. He believed every case of undescended testicle should be operated upon.

Dr. GRANT replied that after complete removal of the growth the *x*-rays and Coley serum should be used for prophylactic reasons.

Chronic Appendicitis. — Dr. F. G. CONNELL of Oshkosh, Wis., read this paper. He reported operating with unsatisfactory results upon forty-eight cases of apparent chronic appendicitis. There were burning sensation, tenderness in the right lower quadrant, umbilical region or elsewhere, general ptosis, gurgling in the lower right quadrant, no leucocytosis, and a ptosed and dilated ascending colon. Twenty-seven were submitted to a second operation. Of these, fifteen were unimproved and one died. The pain in such cases was due to something besides the appendix.

Dr. H. A. BLACK of Pueblo, Col., said that the *x*-ray, test-meal, hematemesis, and the absence of pain and tenderness did not exclude chronic appendicitis. Pyloric spasm was often present in chronic appendicitis and might be due to a hypertension, rather than a hypersecretion.

Dr. LAPLACE of Philadelphia said that there might be a chronic form of transudation of the toxins through the cecum.

Oration on Surgery—Surgical Aspects of the Industrial Accident Insurance.—Dr. EMMET RIXFORD of San Francisco read this paper. The principle of assessing the employer for the surgical care of the employed was of German socialistic origin. Most of the European countries had passed such laws. Thirty-one of the forty-eight states had made laws for workmen's compensation. Many countries enforced compulsory insurance to be carried by the employer, employee, and the State in favor of the employed. He believed the movement inevitable and that its benefits would include checks on lodge-practice, contract-practice, hospital, and patent medicine evils. The industrial commissions having charge of matters pertaining to the surgical care of injured workmen were powerful. Their tendency was to eliminate mediocre surgery and to encourage careful work. Sixty per cent. of the returns for injury went to the workman and 40 per cent. to the physician. There were only three mal-practice suits on record in the past two years. The unions tended to favor union-chosen physicians rather than men chosen by the State for surgical excellency. Experts were employed by the commissions for the special problems.

Complications and Sequellæ of the Operation for Inguinal Hernia. — Dr. LINCOLN DAVIS read this paper. There were 1,500 herniæ operated at the Massachusetts General Hospital between October, 1908, and December, 1914, by seventy-five different surgeons. There were 1,756 distinct operations. Of these, 834 were Bassini, 15 Halsted, and others according to Ferguson. General anesthesia was administered in 1,309, spinal in 108, local, combined, in 6, and local alone in 75. There were accidents to the bladder in 2, to the vas in 7, to the bowel in 2, and 8 deaths. The mortality was 0.53 per cent. Sixty-six recurred or 3.7 per cent. (or 8 per cent. traced). These were divided about equally between the Bassini and Ferguson methods.

Dr. H. O. MARCY of Boston was one of the pioneers in hernial surgery. He had had about 3 per cent. returns in 1000 cases.

Dr. D. N. EISENDRATH of Chicago suggested using adrenalin, one drop instead of four or five, to the ounce in local work. He thought recurrences were sometimes due to neglecting an occasionally present pantaloon sac, or to leaving a direct or indirect sac when both occur simultaneously. Pain was sometimes caused by the inclusion of nerve fibers in the sutures.

Dr. DAVIS believed there was a preexisting congenital sac in all so-called traumatic herniæ. The figures for the local operations might be too high. The infiltration of the tissues might interfere with firm closure.

The Surgical Problem of Symptomless Hematuria, Its Causes and Surgical Relief.—Dr. R. L. PAYNE, JR., of Norfolk, Va., read this paper. He based his report upon eleven human and five dog instances of hematuria. He found in those cases where the kidney was removed and studied, inflammatory changes in the cortico-medullary portion and dilated veins in the medullary portions. He held that the inflammation interfered with the venous return and forced the already distended veins to empty into the pelves. The treatment included nephropexy for the displaced kidney, decapsulation, nephrotomy, and nephrectomy (too radical). The non-operative treatment included the use of styptics, adrenalin, and sera.

Dr. H. A. ROYSTER of Raleigh, N. C., said a colleague had hematuria only when he used tobacco. The pathological changes might be those represented, or none at all, or incipient tuberculosis. Decapsulation was of no account. Instead of sutures, gut might be wrapped about the kidney after exploratory nephrotomy.

Dr. J. S. HORSLEY of Richmond, Va., said painless hematuria was due to stone, tuberculosis, or hypernephroma and to the changes described. The straight suture caused less necrosis than the mattress and was as efficient.

Dr. PAYNE replied that decapsulation cured probably by setting up a thrombosis.

A Consideration of Fractures and Other Injuries of the Hip.—Dr. A. R. MACAUSLAND of Boston read this paper. He divided the fractures into separations of the upper femoral epiphyses, fractures of the necks, and fractures between the trochanters. He favored Whitman's abduction method for fractures of the neck. The flexion method was not as comfortable, especially for the old. Operative measures (nails, plates, etc.), were not necessary for acute cases. Reduction of fracture without an anesthetic was possible only in those that could be speedily reduced. For the intratrochanteric variety, plaster fixation in abduction was the best. Of fifty cases, he had thirty-two reports which were satisfactory. Slides.

Nail Extension in Fractures of the Lower Extremity. —Dr. J. C. A. GERSTER of New York read this paper. The nail extension was indicated when the usual traction or plaster methods failed or could not be employed; in badly compounded recent fractures with extensive abrasions and injury to the soft parts, and in old malunions with much shortening. Nail extension reduced the number of cases in which open operation was indicated. Pain was prevented by drawing the skin upwards when inserting the nail and infection was prevented by not passing nail into joint cavity or through the epiphyseal line. In thirty cases, the nail holes healed completely under wet dressings.

Nails and Screws Through Joint Surfaces in Autografts and in Fractures into Joints.—Dr. A. T. MANN of Minneapolis read this paper. In twenty experimental cases the author had lost no knee from infection. The dogs did so well that it was difficult to ascertain the operated knee. The cartilage grew into the grooves caused by the screws, appearing first as hyaline and later as the fibrous variety. This was finally replaced by fibrous tissue. He showed slides of the autografts, fractures, and reactions to the nails and screws.

Dr. C. E. THOMPSON of Scranton, Pa., said that fractures of the femoral necks were badly treated. Some believed they should be left alone; others that they would not heal as other fractures. Operation should not be attempted at the time of fracture.

Dr. R. S. SAYRE of New York said the joints presented showed evidences of erosion. The two human cases appeared to be good results. The Steinman pin worked well in some cases as Gerster had indicated.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Two Hundred and Seventy-Ninth Regular Meeting, Held Friday, May 5, 1916.

DR. JOHN S. THACHER, PRESIDING.

Unusual Paralysis in Upper Spinal Region Following Anterior Poliomyelitis. — Dr. VIRGIL P. GIBNEY presented this patient, who was a boy, 11 years of age, admitted to the Hospital for Ruptured and Crippled, April, 1916, on account of deformity of right foot. Had "fever" at four years lasting 24 to 36 hours. Patient never had braces or operation. Both arms were included in paralysis at onset, but they had so improved that patient had some use of them, under electrical treatment. The reactions now were—right—supraspinatus, infraspinatus, rhomboideus major and minor, latissimus dorsi deltoid, pectoralis major and minor, teres major and minor and levator scapuli, reaction of degeneration; serratus magnus gone; left—supraspinatus, rhomboideus major and minor, deltoid, pectoralis major and minor, serratus magnus, teres major and minor, and levator scapulæ, reaction of degeneration; latissimus dorsi gone altogether; trapezius right and left sides practically normal. The paralysis just took

in the upper group of muscles. The boy now had his foot in plaster of Paris, but would probably have to have a piece of bone taken out of the astragalus to get the ankle straight.

Some Observations on Hemolytic Jaundice. — Dr. GEORGE E. BREWER read this paper (see page 1).

Dr. BREWER added that both patients shown had hemolytic jaundice. Both were jaundiced at the time of operation. One patient had a good deal of pigmentation of the skin. There was very little fragility of the blood in one case and practically none in the other. Dr. Longcope had had the cases a long time under observation. The second case had a blood fragility of 7 which went down to 4. The normal was 4.5.

Dr. W. GILMAN THOMPSON said that the operation of splenectomy used to be considered one of considerable severity, but now it was performed very successfully and the cases remained successful after many years. He would like to ask the size of the spleen in Dr. Brewer's cases.

Dr. BREWER said he did not recall the actual size, but it was about three times the size of the normal spleen, and weighed 11-12 grams. It was an inch below the costal border. One had a slight adhesion, but neither was what would be called an adherent spleen.

Dr. J. S. THACHER asked if the veins were very large, and if the liver was normal.

Dr. BREWER said the veins were very tortuous and extremely friable, and the livers were slightly enlarged.

Dr. W. GILMAN THOMPSON asked if gallstones were usually associated with these cases.

Dr. F. S. MEARA asked if the pain was usually referred to the spleen.

Dr. BREWER said that the pain was sometimes purely epigastric, and sometimes radiated to the left shoulder.

Dr. J. W. BRANNAN said he would like to ask what was meant by fragility of the blood.

Dr. F. S. MEARA said that the cells were more susceptible to being broken down when the normal salinity of the blood was changed. A very little diminution in the normal salt content of the blood would produce breaking down of the red cells. The severity of the condition could be read by the susceptibility of the cell to the changes in the saline constituents.

Dr. BREWER said the test was made by finding the percentage of saline at which hemolysis began. The test was best made with washed cells. The cell surrounded by blood plasma was rather protected. The normal 0.45 solution of salt would hemolyze normal blood, whereas 0.7 showed more susceptibility.

Dr. BRANNAN asked what was the theory of the operation.

Dr. BREWER said it was that normal hemolysis took place largely in the spleen; when the red cells had done their work they became degenerated. The function of the internal secretion of the spleen was to destroy red cells. If there was a condition of hypersplenism, that is, where the hemolysis was more rapid, a larger number of red cells were destroyed than normal. The hemoglobin became split into two substances, hematin, which was deposited in the liver and sometimes bilirubin, which under ordinary conditions was taken up by the liver and excreted in the bile, but if it occurred in excess it entered into the intestine, and there changed to hydrobilirubin. This later became urobilin and was excreted in the urine.

Dr. BRANNAN said then was the spleen overdoing its function?

Dr. BREWER said yes: the pigments were not taken care of normally and were found in the blood.

Dr. BRANNAN asked why this condition caused so much harm.

Dr. BREWER said that the rapid hemolysis was the cause of grave anemia. In some severe cases hemoglobinuria occurred. Eppinger had commented upon the hemolytic activity, and upon the intoxication by means of products being thrown into the blood. There followed fever, chills, and all the symptoms of an intoxication. This might quiet down and the temperature again become normal.

Dr. MEARA said that Pearce had reported decreased fragility of the red cells from splenectomy.

Dr. BREWER said in one case reported the spleen was removed for traumatism. In this instance the red cells rose to 7,000,000, and the hemoglobin to 110 per cent.

Dr. BRANNAN said it used to be supposed that the spleen was very necessary for the body.

Dr. BREWER said it was a good thing to have but when it was pathological it was better to remove it.

Dr. GILMAN THOMPSON said that there must be some modification in the bile which produced gallstones so frequently as a complication.

Dr. BREWER said that the condition was certainly associated with gallstones in a good many cases.

Dr. J. S. THACHER said that it used to be maintained that the bile in cases of hematogenous jaundice was thickened and that the jaundice was due to obstruction of the minute bile ducts by the thickened bile.

Dr. BREWER said he had operated on the bile ducts first, but that did not give the explanation.

Dr. FORDYCE asked what was the ultimate fate of these cases.

Dr. BREWER said that the longest record was 23 years. The patient was perfectly well. A good many cases were never operated on. In the later stages many cases were reported with pernicious anemia. This also was due to excessive hemolysis.

Dr. BRANNAN asked if this was a very recent procedure.

Dr. BREWER said it dated back as far as 1903. The first operation was done for pernicious anemia. The patient also had jaundice. The jaundice entirely cleared up two weeks after operation.

Dr. MEARA said that they had two interesting cases in the ward, of so-called Banti's disease with splenomegaly and anemia. The first patient was operated upon by Dr. Hartwell. It was a very advanced case. There was recurrent ascites and the spleen was very large. The liver could be readily palpated. There was very advanced cirrhosis. He believed the patient was still living. The other case was one of very marked splenomegaly with marked secondary anemia, with 2,000,000 red cells. There was no change in the character of the cells. It was now general opinion that these were early cases of Banti's disease. In this case with ascites the fluid was injected into a guinea pig; the result had not been reported, but the man had evidently a tuberculous spleen. The ascites might be from tuberculous peritonitis. The man was sent for operation as it was justified from the standpoint of the peritonitis.

Dr. BREWER said he had never seen a tuberculous spleen. There were two or three in the records.

Dr. MEARA said it would be called splenic anemia on the old criteria, but this was tuberculosis.

Dr. BREWER said in another case he had to mention, he did a gall-bladder exploration. The patient had had jaundice 20 years, and was then 37. Health had been pretty good until recent years. He had explored the gall-bladder region and had found nothing. There were spots in the liver which were supposed to be adrenal rests, but this was later found to be incorrect. The patient afterward came in on Dr. Evans' service. He diagnosed the case at once as a hemolytic jaundice. Dr. Peck operated on the natient who had been perfectly well ever since. In some cases gallstones were found, and the removal of these gave no relief. The cases cleared up with splenectomy. Another case with a peculiar history, was one where another surgeon explored the gall bladder and nothing was found. The patient was closed up and there was no improvement. At a second operation gallstones were found. Thus in two cases gallstones were found on second operation and not on the first. One case at the Presbyterian Hospital, on Dr. Longcope's service had the symptoms of obstructive jaundice, with high colored urine at times. This patient had also an enlarged spleen. It was finally concluded that she had obstructive jaundice. She was operated on and the gall bladder was very difficult to expose, as it was greatly dilated and full of bile. It took very long to dissect out the gall bladder and the ducts never were exposed so as to be palpated. He did a cholecystenterostomy. The patient made a perfectly good recovery. Bile appeared in the stools. In spite of that for two or three weeks there was no improvement in the jaundice. He thought perhaps it was a double lesion. In some cases, a negative exploration, with the handling involved, might start a small hemorrhage, which acted as a foreign body, and this might account for stones being found on second operation.

Dr. C. L. GIBSON said that he had often not seen any improvement in the jaundice for two or three weeks.

Dr. BREWER said that he felt that there should be an immediate change in the jaundice.

Dr. GIBSON asked what had been Dr. Brewer's experience in regard to this anastomosis.

Dr. BREWER said that he had done very few cholecystenterostomies. In his opinion this was a very dangerous operation.

Dr. THACHER asked if the patients usually died.

Dr. BREWER said yes.

Dr. GIBSON said he operated in a case of this kind six weeks ago and made a perfectly successful anastomosis. It was a case of carcinoma of the pancreas. Six weeks after operation the jaundice began to clear up and bile to go through. He had had that experience two or three times.

Dr. BREWER asked Dr. Gibson if he did not think that chronic obstructive jaundice cases got bronzed instead of bright yellow. There was a difference in the jaundice. He knew a woman who had hemolytic jaundice seventeen years, and was bright yellow.

Dr. THACHER asked if that was not similar to the color of pernicious anemia.

Dr. BREWER said yes, but it was brighter. It was due to hemolysis.

Dr. GIBSON said it was a curious thing in diagnosing cases of pelvic compression; the patient would usually say that he had had jaundice and it had remitted.

Dr. BREWER said that he did not think one could place much reliance on a personal record. In cases of carcinoma of the breast, patients would say that the tumor varied in size. There was one other point to be mentioned in connection with Banti's disease. (He thought the three lesions were closely allied.) There was the theory that the original lesion was a phlebitis of the splenic vein. In some cases of Banti's disease there was a thickening and tortuosity of the veins often with calcarous plates, originating in infection.

Dr. MEARA said he had read one notice lately of such a paper, but that was all that he had seen in the literature.

Dr. THACHER said that it had been suggested that cirrhosis of the liver arose in pylophlebitis. Of all the cases of hemolytic jaundice operated on, it seemed that only two deaths occurred. Were those two attributed to operation?

Dr. BREWER said that in one case death was directly due to operation on a poor subject. The other case was cited as having died from uremia, but as the death occurred pretty quickly after operation, he thought that it might have been post operative.

Dr. GILMAN THOMPSON said in illustration of the difficulties of gallstone diagnosis, he saw a woman last November who had recurrent cramps in the legs. While under observation she suddenly developed an apparent cholecystitis. She had pain over the gall bladder and a distinct mass was palpable. She had fever, leucocytosis and reflex vomiting. She was taken to Roosevelt Hospital. Dr. Peck operated and found nothing in the gallbladder but a cirrhous carcinoma of the liver, which had given no suspicion of its presence and the organ was not enlarged and her nutrition was extremely good. Since the exploration made last January the liver continued to enlarge and now reached the umbilicus, large tumor masses being palpable, but after the patient was sent home she got on fairly well with only occasional attacks of reflex vomiting. She had had continuous high temperature for four months ranging from 99.8° to 102°. The hemoglobin at the time of the supposed gallstone attack was 50 per cent., and it had gone up to 80 per cent. since. She was able to digest a variety of food and she presented an interesting illustration of maintenance of excellent nutrition despite a rapidly growing carcinoma.

Dr. BRANNAN said she was apparently better for the operation.

Dr. THACHER asked Dr. Thompson if he thought carcinomas grew more slowly in elderly people.

Dr. THOMPSON said it depended upon where they were situated. He thought there was often good nutrition for some time in a certain group of hepatic carcinomata.

Dr. BRANNAN asked if in this case any of the growth was removed.

Dr. THOMPSON said no: there was no convenient nodule. Dr. Peck thought the best thing was to make the operation as short as possible. The woman had had a recent broncho pneumonia and it was not thought advisable to keep her under ether long.

Dr. THACHER asked if Dr. Brewer thought if age made any difference in the rapidity of breast carcinoma.

Dr. BREWER said very often in elderly people it grew slowly.

Dr. FORDYCE asked was this case mentioned by Dr. Thompson primary carcinoma?

Dr. THOMPSON said he supposed pathologists would find a nodule somewhere else as a primary focus, but clinically it was solely hepatic.

Dr. THACHER said occasionally it originated in the liver.

Dr. GIBSON said he used to teach that there was no such thing as primary carcinoma of the liver. It was supposed to be carcinoma of the bile ducts. He did not see how one could get it without epithelium, and there was no epithelium in the liver.

Dr. BREWER asked what was the origin of the liver cells. Were they mesoblastic? He said he was much surprised to hear Dr. Gibson say that there was no epithelium in the cells of the liver.

Dr. BRANNAN asked what Dr. Thompson said to that.

Dr. THOMPSON said he was willing to admit that this growth might have originated in the gall-bladder, but there was no jaundice.

Dr. THACHER said that it might be called cancer of the liver even if it originated in the bile ducts.

Dr. BREWER said he would like to mention one case of obstructive jaundice due to pressure of a tuberculous lymph node on the bile duct. He had also seen one case due to Hodgkin's disease.

Dr. MEARA asked if it was adherent to the gallbladder.

Dr. BREWER said it was on the junction of the bile duct and common duct.

Dr. THACHER said he saw the autopsy of a case where the obstruction was due to a mass of cicatrical tissue which appeared to be of syphilitic origin.

Dr. GIBSON said he operated on a case due to lymphosarcoma of nodules on the bile duct. He did a cholecystenterostomy and the patient made a good recovery. He operated on another patient without jaundice and took out the nodule for examination. The pathologist made a similar report as on the first case. One case got well; the other died.

Dr. THACHER said that sarcoma was often the most difficult diagnosis to make, and especially lymphosarcoma.

Dr. J. C. ROPER said that one of Dr. Brewer's patients, Miss L.., was watched for years. She had no free hydrochloric acid at any time.

Dr. BREWER said that she had sour vomiting, and at one time the case simulated gastric ulcer.

Dr. ROPER said that there was not so large a fragility of the cells as in the other patient. The fragility test depended on the amount of water used. It was a question of surface tension.

Dr. BREWER said that washing the cells made a difference.

Dr. ROPER said the patient had an attack of jaundice that looked like an infection. The cells dropped to two million in a short time. She had hemoglobinuria. There was temperature, and swollen joints, which were relieved following salicylates.

Dr. MEARA said the temperature might be accounted for by the hematin.

Dr. ROPER said that one patient showed no excretion of urobilin. It was a puzzling thing how she got rid of it.

Dr. BREWER said that Dr. Longcope had stated that if one could have seen the patient during the febrile attacks, more blood fragility might be noted.

Dr. ROPER said that the patient came to the New York hospital. He did the nitrogen partition and never found anything abnormal. He did not believe that the cholesterin content of the blood and the iodine index was done.

Dr. BREWER said that he had had the cholesterin content done. It was normal. He said he would like to ask Dr. Roper what the vital stain indicated.

Dr. ROPER said that the blood might show more chromophilic degeneration than normal blood.

Dr. BREWER asked if these were degenerating or new cells.

Dr. ROPER said that one man might argue one way and one another. The normal percentage was 1.3.

Dr. THACHER asked if that indicated activity of the hemapoietic function.

Dr. MEARA said it indicated an attempt to restore the cells to the normal.

PHILADELPHIA NEUROLOGICAL SOCIETY.

AT a stated meeting held April 28 Dr. WILLIAM B. CADWALADER presented a communication entitled "Occasional Resemblance of Tabes Dorsalis to Disease of the Pituitary Gland." He referred to observations of this character in the literature, and he related the details of a similar case under his observation. The patient

was a man 51 years old, who presented diplopia, reduction in the visual fields, optic atrophy, and absence of knee-jerks and Achilles jerks. There was, however, an increase in fat-deposition and absence of hair in various situations, enlargement of the breasts, increased hunger and thirst, increased tolerance for sugar carbohydrates. X-ray examination disclosed changes in the sella turcica suggestive of the presence of a new growth involving the hypophysis.

Dr. ALFRED GORDON presented "A Case of Syringomyelia." The patient was a colored man, 58 years old, who presented weakness and wasting in the upper extremities, with contractures and deformity of the fingers and loss of part of one finger by spontaneous and painless amputation. Common sensibility was preserved, while sense of pain and temperature-sense were impaired and the knee-jerks were increased.

Dr. JOHN H. W. RHEIN presented "A Case of Wasting of the Muscles of the Left Side of the Body Following Injury of the Right Side of the Brain." The patient was a man, 24 years old, who at the age of thirteen received a bullet-wound on the left side of the skull, the missile injuring and lodging in the right side of the brain. Several operations were performed but the bullet was never secured, and *x*-ray examination disclosed its presence now at the base of the skull, apparently in the posterior fossa. The striking feature was the notable atrophy of the musculature on the left side of the body, with a corresponding degree of weakness, associated with slight exaggeration of the knee-jerks.

Drs. E. M. AUER and GRAYSON PREVOST MCCOUCH presented a communication entitled "The Pathological Findings in Two Cases of Paralysis Agitans." The changes observed consisted essentially in evidences of rarefaction of the basal ganglia of the brain, apparently not related to the perivascular spaces.

Dr. WILLIAM G. SPILLER reported "A Case of Association of Severe Anemia with Tabes Dorsalis." The patient had been under observation only a few days, and he presented apparently only the ordinary symptoms of tabes dorsalis. He was ill nourished and pallid, but a blood examination was not made. On post-mortem examination, however, in addition to the lesions of tabes there were found the characteristic changes associated with profound grades of anemia. The two processes were entirely independent one of the other.

Dr. FREDERICK P. CLARKE presented a communication entitled "A Study of Acroataxia and Proximoataxia in Tabes Dorsalis." He was unable to demonstrate that proximoataxia preceded acroataxia in cases of tabes in contradistinction to subacute mixed sclerosis due to profound anemia, in which it has been maintained the reverse order of development takes place.

Dr. OWEN COPP presented a communication entitled "The Psychiatric Needs of a Large Community." He pointed out that insanity is evidence of disease, and it must be studied in precisely the same way as are other morbid affections. To this end a well-equipped and well-administered psychiatric clinic and hospital are required, with abundant modern laboratory facilities and an adequate staff of workers in the several fields of medicine. The patients must be treated with a view to their recovery, and after-care must be directed to the prevention of recurrence. Prophylactic work must be done to prevent the ill effects of toxic agents, such as alcohol, as well as those of infectious, such as syphilis, and segregation must be practised in a rational manner to prevent reproduction of their kind by the mentally deficient and the insane. Furthermore, adequate instruction must be given in the medical schools so that the general practitioner shall be competent to make an early diagnosis and promptly apply the appropriate treatment.

Determination of Sex.—J. S. Frecborn states that as a result of study of 1,000 obstetrical cases he was able to foretell the sex previous to birth in 97.5 per cent. Nearly all conceptions during the first half of the intermenstrual period result in female offspring, boys resulting from conceptions in the latter half. Hence sex control should be a simple matter—the mere practice of abstinence at stated times. To formulate a law: have marital relations only during the first ten days after menses when girls are desired, and during the first ten days before menses when boys are sought. There are certain sources of fallacy which must be borne in mind; for example, the woman may wrongly give the date of menstruation.—*Canadian Practitioner and Review.*

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

STATE MEDICAL BOARD OF THE ARKANSAS MEDICAL SOCIETY.

November 9 and 10, 1915.

ANATOMY.

1. Name the articulations of the frontal and occipital bones. What bones articulate with the radius?
2. Name divisions of the vertebral column, giving number of bones in each division. What are distinguishing characteristics of cervical vertebrae?
3. What are the relations of the brachial artery? Name its branches.
4. What spinal nerves enter into the formation of the anterior crural nerve, and what muscles does it supply?
5. Describe the origin, course and distribution of the renal arteries.
6. Name the cavities, openings, and valves of the heart.
7. Name the coverings of a femoral hernia.
8. Give origin and insertion of the following muscles: Biceps, pectoralis minor, and popliteus. Give blood and nerve supply of each.
9. Name the arteries and nerves which supply the duodenum. What veins drain this region?
10. What structures are severed in an amputation about the middle third of the thigh?

PHYSIOLOGY.

1. (a) Give composition of blood; (b) function of blood as a whole; (c) red cells; (d) leukocytes.
2. Trace the course of the blood, (a) complete cycle, (b) in adult, (c) in fetus.
3. Give the causations and describe the occurrence of dyspnea.
4. Where and how are bread and butter digested?
5. Compare the work done by the liver on a protein diet with that done on a carbohydrate diet.
6. What are the most prominent differences between the composition of the blood plasma and that of the urine?
7. Why is the lymphatic system so essential to the human body?
8. Name parts of (a) the small intestines, (b) large intestines. Give name and location of the glands found in the small intestines.
9. How is the temperature of the body regulated and sustained?
10. What is the function of the medulla oblongata?

CHEMISTRY.

1. (a) What is an element? (b) Name five with symbols.
2. (a) Give two methods of preparing oxygen. (b) Give equation of one method.
3. What is an acid, a salt, a base? Give example of each.
4. Name the elements in the halogen group.
5. Describe Marsh's test for arsenic.
6. What do you understand by specific gravity?
7. Complete the following: $NaCl + H_2SO_4 = ?$ $Zn + HCl = ?$ $AgNO_3 + HCl = ?$
8. Describe Fehling's test for glucose, and explain chemical reaction.
9. What is the reaction between granulated sugar and Fehling's solution?
10. Give the various steps in making a urinalysis.

MATERIA MEDICA.

1. (a) What are antiseptics? (b) Disinfectants? (c) Give an example of each.
2. Define a laxative and tell how it acts.
3. Name the alkaloids of nux vomica.
4. (a) Give the properties of chloroform. (b) Name several preparations of chloroform.
5. What evils may result from chemical incompatibility in prescriptions?
6. (a) What is the source of digitalis? (b) Give symptoms of digitalis poisoning.
7. (a) What is the source of ergot? (b) Give physiologic action of ergot.
8. (a) Name six official preparations of mercury. (b) Give briefly the properties, uses and dose of each.
9. Name the principal alkaloids of Papaver somniferum.
10. Classify the following drugs according to their physiologic action: Sodium chloride, sodium hydroxide,

potassium citrate, adeps lanæ hydrosus, epinephrin, fel bovis (ox gall), and ferri carbonas.

THERAPEUTICS.

1. How do the following drugs act in intermittent malarial fever: Quinine, methylene blue, and eucalyptus?
2. What remedies should be used for hemorrhage from mucous surfaces?
3. What are the conditions in cystitis that contraindicate the use of alkaline diuretics?
4. What drugs would you use hypodermically to stimulate the heart; to produce emesis; to control hemorrhage?
5. Give the therapeutic application of drugs in the different stages of pneumonia.
6. Mention the remedy which will arrest the secretion of milk, and state how it should be employed.
7. What are the therapeutic uses of glycerin?
8. Describe the therapeutic uses and dangers of chloral hydrate.
9. Differentiate the physiologic effects on the gastric juice and on the urine of the administration of potassium bicarbonate before and after meals.
10. What are the therapeutic uses of tartar emetic?

PATHOLOGY.

1. Give analysis of the urine of patients affected with autointoxication.
2. A persistent low blood pressure is pathognomonic of what class of diseases?
3. In what diseases do we find arteriosclerosis, and to what conditions does it predispose?
4. What is the significance of an absence of chlorids in the urine?
5. Explain cause and describe minutely the formation of an epithelioma.
6. Explain the formation of pus.
7. Define leukemia, and discuss briefly the clinical phases in its progress.
8. What pathologic condition is induced by chronic infections of: the nose, throat, teeth, or their accessory sinuses?
9. What is the pathologic significance of vertigo?
10. (a) When do secondary and tertiary symptoms of syphilis appear? (b) What is the significance of nocturnal headaches in syphilis?

ANSWERS.

ANATOMY.

1. The *frontal bone articulates* with: Two parietal, sphenoid, ethmoid, two nasal, two superior maxillary, two lacrymal, and two malar.

The *occipital bone articulates* with: Two parietal, two temporal, sphenoid, and atlas.

The *radius articulates* with: Humerus, ulna, scaphoid, and semilunar.

2. The vertebral column is divided into: Cervical division, with seven bones; dorsal, or thoracic, with twelve bones; lumbar, with five bones; sacral, with five bones, and coccygeal, with four bones.

The *cervical vertebræ* are distinguished by possessing a foramen in the transverse processes. Further, they are smaller than those in the other regions; they have no facets for the ribs; the spinous processes are generally short and bifid; the spinal foramen is large and triangular; the superior articular process is directed upward and backward, and the inferior articular process is directed downward and forward.

3. Brachial artery. *Relations. In front:* Skin, fascia, bicipital fascia, median basilic vein, median nerve, coraco-brachialis, and biceps. *Behind:* Triceps, musculospiral nerve, superior profunda artery, coraco-brachialis, and brachialis anticus. *Externally:* Median nerve (above), coraco-brachialis, and biceps. *Internally:* Internal cutaneous nerve, ulnar nerve, median nerve (below), and basilic vein. *Branches:* Superior profunda, inferior profunda, nutrient, anastomotica magna, and muscular.

4. The *anterior crural nerve arises* from the second, third and fourth lumbar nerves, and (sometimes) also from the first or fifth lumbar. It *supplies* the iliacus, pectineus, sartorius, vastus externus, vastus internus, crureus, rectus femoris.

5. The *renal arteries* arise from the abdominal aorta, just below the superior mesenteric artery; they pass out at right angles to the aorta, and cross the crus of the diaphragm. The right is longer than the left, passes behind the inferior vena cava, the right renal vein, the head of the pancreas, and the duodenum. The left passes behind the left renal vein, the body of the pancreas, and is crossed by the inferior mesenteric vein. Before reaching the kidney each artery divides into four or five branches.

6.

HEART.

Cavities.	Openings.	Valves
Right auricle.	Superior vena cava. Inferior vena vaca. Coronary sinus. Foramina of Thebesius. Right auriculo-ventricular.	Eustachian. Coronary.
Left auricle.	Four pulmonary veins. Left auriculo-ventricular.	
Right ventricle.	Right auriculo-ventricular. Pulmonary artery.	Semilunar. Tricuspid.
Left ventricle.	Left auriculo-ventricular. Aortic.	Mitral. Semilunar.

7. *Coverings of a femoral hernia,* from without inward, are: Skin, superficial fascia, cribriform fascia, crural sheath, septum crurale, subserous tissue, and peritoneum.

8. Biceps. *Origin:* Apex of coracoid process of scapula, upper margin of glenoid cavity of scapula. *Insertion.* Tuberosity of radius. *Blood supply:* Brachial. *Nerve supply:* Musculocutaneous.

Pectoralis minor. *Origin:* Third, fourth, and fifth ribs, and from aponeurosis of intercostal muscles. *Insertion:* Coracoid process of scapula. *Blood supply:* Acromial thoracic, long thoracic, superior thoracic. *Nerve supply:* Anterior thoracic.

Popliteus. *Origin:* External condyle of femur and posterior ligament of knee joint. *Insertion:* Above the oblique line on posterior surface of shaft of tibia. *Blood supply:* Popliteal. *Nerve supply:* Internal popliteal.

9. Duodenum. *Arteries:* Pyloric and pancreaticoduodenal (from hepatic) and inferior pancreaticoduodenal (from superior mesenteric). *Veins:* Superior and inferior duodenal, which pass into the superior mesenteric and portal veins. *Nerves:* From solar plexus.

10. *Structures severed in an amputation about the middle third of the thigh:* Skin, fascia, tensor vaginæ femoris, femoral artery and vein, profunda femoris, external circumflex vessels, superficial obturator nerve, external cutaneous nerve, anterior crural nerve, deep obturator nerve, small and great sciatic nerves, adductor longus, sartorius, gracilis, pectineus, rectus femoris, adductor brevis, adductor magnus, semimembranosus, semitendinosus, crureus, vastus internus, vastus externus, biceps femoris, and the femur.

PHYSIOLOGY.

1. Blood. *Composition:* Plasma and corpuscles. The *plasma* consists of water and solids (proteids, extractives, and inorganic salts). The *red corpuscles* consist of water and solids (hemoglobin, proteids, fat, and inorganic salts). The *white corpuscles* consist of water and solids (proteid, leuconuclein, lecithin, histon, etc.). There are also *platelets,* which are very small, colorless, irregular shaped bodies, about one-fourth the size of the red corpuscle.

Functions: The *red blood cells* carry oxygen from the lungs to the tissues. The *white blood cells:* (1) Serve as a protection to the body from the incursions of pathogenic microorganisms; (2) take some part in the process of the coagulation of the blood; (3) aid in the absorption of fats and peptones from the intestine, and (4) help to maintain the proper proteid content of the blood plasma. The function of the *platelets* is not determined; it is possible that they take some part in the coagulation of the blood. The *plasma* conveys nutriment to the tissues; it holds in solution the carbon dioxide and water which it receives from the tissues, and takes them to be eliminated by the lungs, kidneys, and skin; it also holds in solution urea and other nitrogenous substances that are taken to and excreted by the liver or kidneys.

2. "The left ventricle pumps the arterial blood

through the large arteries, the small arteries, and the arterioles into the systemic capillaries. For the most part between the capillaries and the tissues is the tissue fluid, and across this the tissues acquire the oxygen from the arterial blood, and return carbon dioxide to the blood in the capillaries. The blood which leaves the tissues is venous. The venous blood returns from the capillaries through the small veins into the larger veins, and the largest veins pour the blood back into the right auricle. It will thus be seen that the right side of the heart is occupied with the pulmonary circulation, and the left side of the heart with the systemic circulation. The right auricle receives the venous blood as it returns from the tissues, and transmits it to the right ventricle. The function of the right ventricle is to pump the venous blood through the pulmonary arteries into the lung capillaries, where the venous blood becomes oxygenated. The oxygenated blood returns by the pulmonary veins to the left auricle, and the arterial blood is then received into the left ventricle."—(Lyle's *Physiology*.)

Differences between the fetal circulation and that of the adult: In the *fetus* there is direct communication from the right auricle to the left auricle by the foramen ovule; the Eustachian valves are larger, the heart is relatively larger; there is communication between the pulmonary artery and the descending aorta by means of the ductus arteriosus; there is communication between the internal iliac arteries and the placenta by means of the umbilical or hypogastric arteries; and the presence of the ductus venosus which unites the umbilical vein and the inferior vena cava.

3. *Dyspnea* may be caused by diminution of oxygen or excess of carbon dioxide in the blood. "As soon as the blood in the body becomes more venous than ordinarily, in consequence of the amount of oxygen sinking below normal, the respiratory movements become quicker, and both inspiratory and expiratory efforts are increased by bringing extra muscles into play. This condition of difficult beathing is termed dyspnea. As the blood becomes more and more deficient in oxygen, the respiratory efforts become more labored, the expiratory movements becoming more marked than the inspiratory. The expiratory efforts become convulsive in character and all the muscles of the body presently take part in the convulsions. In the last stage the convulsions cease, coma sets in, the pupils dilate, the conjunctivæ are insensible, while at intervals respiratory efforts, chiefly inspiratory, are made." (Ashby's *Notes on Physiology*.)

4. *Bread* consists of proteid, fat, carbohydrate, salts, and water. *Butter* consists of fat, a little proteid, and water. In the *mouth*, the ptyalin of the saliva changes starch into dextrin and sugar; in the *stomach*, the proteids are changed into proteoses and peptones; in the *small intestine*, the proteids are further changed into proteoses and peptones and afterwards into polypeptides and amino-acids; starches are converted into maltose; fats are emulsified and saponified.

5. *Action of liver on protcid:* It removes the amino group from the amino-acids absorbed, converting these latter into oxyacids and transforming the ammonia into urea.

Action of liver on carbohydrate: It stores glycogen, converts it into dextrose and returns this latter to the blood stream and thus keeps a constant percentage of sugar in the blood.

6. *Composition of urine:*

	(PARTS IN 1000)	
Water	950.00	
Urea	28.00	
Uric acid	0.60	
Hippuric acid	0.35	Organic
Creatinin	0.65	
Extractives	8.00	
Sodium chloride	8.00	
Phosphoric acid	2.00	
Sulphuric acid	1.25	
Lime (CaO)	0.25	Inorganic
Magnesia (MgO)	0.30	
Potash (K_2O) and soda (Na_2O)	0.60	
Total	1000.00	

As compared with urine, *plasma* contains less water and more solids, more organic matter, less urea, gases (oxygen, nitrogen, carbon dioxide), hormones and enzymes.

7. *Function of lymph:* (1) It conveys nutriment to all cells not directly reached by the blood; (2) in the intestines, it absorbs nutrient material (chiefly fat) and pours it into the blood stream for distribution; (3) it takes certain waste matters to the blood to be later eliminated by the lungs, kidneys, and skin.

Without the lymphatic system the above functions would be in abeyance.

8. *Parts of the small intestine:* Duodenum, jejunum, and ileum.

Parts of the large intestine: Cecum (with appendix), ascending colon, transverse colon, descending colon, sigmoid colon, and rectum.

Glands of small intestine: Lieberkühn's glands, in duodenum, jejunum, and ileum; Brunner's glands, in duodenum; solitary glands, in ileum chiefly, but also in duodenum and jejunum; Peyer's gland, chiefly in ileum, but also in jejunum, and a few in duodenum.

9. The normal body temperature is *regulated* and *maintained* by the thermotactic centers in the brain and cord keeping an equilibrium between the heat gained or produced in the body and the heat lost.

Heat is produced in the body by: (1) Muscular action; (2) the action of the glands, chiefly of the liver; (3) the food and drink ingested; (4) the brain; (5) the heart, and (6) the thermogenetic centers in the brain, pons, medulla, and spinal cord.

Heat is given off from the body by: (1) The skin, through evaporation, radiation, and conduction; (2) the expired air; (3) the excretions—urine and feces.

10. The *functions of the medulla oblongata* are: (1) It is a conductor of nervous impulses or impressions from the cord to the cerebrum, from the brain to the spinal cord, also of coordinating impulses from the cerebellum to the cord; (2) it contains collections of gray matter which serve as special nerve centers for the following functions or actions; respiration, salivary secretion, mastication, sucking, deglutition, vomiting, voice, facial expression; it also contans the cardiac and vasomotor centers.

CHEMISTRY.

1. (*a*) An *element* is a kind of substance out of which we cannot, by any known means, get any other substance.

(*b*) Oxygen, O; Silver, Ag; Mercury, Hg; Carbon, C; Calcium, Ca.

2. (*a*) Oxygen may be prepared by the decomposition of potassium chlorate; also by the heating of manganese dioxide.

(*b*) $2KClO_3 = 2KCl + 3O_2$.

3. An *acid* is a compound of an electronegative element or residue with hydrogen, part or all of which hydrogen it can part with in exchange for an electropositive element, without the formation of a base. *Example:* Nitric acid HNO_3.

A *salt* is a compound formed by substituting a basylous element for the replaceable hydrogen of an acid. *Example:* Potassium nitrate, KNO_3.

A *base* is a ternary compound which is capable of entering into double decomposition with an acid, to form a salt and water. *Example:* Potassium hydroxide, KHO.

4. The *elements in the halogen group* are: Fluorine, chlorine, bromine, and iodine.

5. *Marsh's test for arsenic:* This test depends on the fact that arsenic hydride is formed when nascent hydrogen acts on a compound of arsenic:

$$H_3AsO_3 + 3H_2 = AsH_3 + 3H_2O.$$

A small flask fitted with thistle funnel and a delivery tube, as for the production of hydrogen, is used; pure zinc and hydrochloric acid are introduced, and after a short time the hydrogen is ignited. It is advisable to cover the flask with a cloth before igniting the gas, as an explosion may happen unless the air has all been driven out. If the materials are pure the hydrogen flame gives no deposit upon a piece of cold porcelain brought into it, but commercial zinc usually contains arsenic. When the purity of the gas is proved, a little solution of arsenite may be poured down the thistle funnel, which will produce a more rapid evolution of gas, and the flame will become larger and perceptibly colored. A piece of cold porcelain depressed upon the flame will be covered with a deposit of metallic arsenic. The films of arsenic are metallic looking in the thicker places, brownish near the edges; they are easily volatilized by heat, and dissolve in solution of bleaching powder. A portion of the glass tube from which the gas is burned should be heated to redness; the gas decomposes and a deposit of arsenic appears on the

tube, which may be identified in a similar way, or may be converted into crystals of oxide by cautious sublimation in an open tube.—(Fisher's *Elementary Chemistry.*)

6. *Specific gravity* of a substance is the weight of a given volume of that substance as compared with the weight of an equal volume of some other substance taken as a standard, under like conditions of temperature and pressure.

7. $NaCl+H_2SO_4=HCl+NaHSO_4$.
$Zn+2HCl=ZnCl_2+H_2$.
$AgNO_3+HCl=AgCl+HNO_3$.

8. *Fehling's test for glucose:* Place in a test-tube a few c.c. of the liquid prepared as stated below, and boil; no reddish tinge should be observable, even after five minutes' repose. Add the liquid under examination gradually, and boil after each addition. In the presence of sugar a yellow or red precipitate is formed. In the presence of *traces* of glucose, only a small amount of precipitate is produced, which adheres to the glass, and is best seen when the blue liquid is poured out.

[The reagent must be kept in two solutions, which are to be mixed immediately before use. Solution I consists of 34.653 gms. of crystallized $CuSO_4$, dissolved in water to 500 c.c.; and Solution II of 130 gms. of Rochelle salt dissolved to 500 c.c. in NaHO solution of sp. gr. 1.12. When required for use equal volumes of the two solutions are mixed, and the mixture diluted with four volumes of water.]

9. Cane sugar either does not reduce Fehling's solution, or reduces it very slowly.

10. *An analysis of urine* includes: Estimation of total quantity passed in twenty-four hours, color, odor, reaction, specific gravity, total solids (by aid of Haeser's coefficient). Then examine for albumin by Heller's test, or by heat and nitric acid (HNO_3); then for glucose by Moore's test, with potassium hydroxide (KHO), or with Fehling's solution, which contains copper sulphate ($CuSO_4$), sodium hydroxide (NaHO), and Rochelle salt ($C_4O_6H_4NaK$); then for blood with potassium hydroxide solution (KHO); then for bile pigments by Gmelin's test, requiring nitric acid (HNO_3); then for indican, using lead acetate [$Pb(C_2H_3O_2)_2$], hydrochloric acid (HCl), ferric chloride (Fe_2Cl_6), and chloroform ($CHCl_3$). Then quantitatively for urea, using solution of sodium hypobromite (NaBrO); for chlorides, with silver nitrate solution ($AgNO_3$); for sulphates, with barium chloride solution ($BaCl_2$). Acetic acid ($C_2H_4O_2$) will be necessary to acidify alkaline urines.

MATERIA MEDICA.

1. *Antiseptics* are agents which prevent or hinder the growth of microorganisms without necessarily destroying them. *Example:* Boric acid.

Disinfectants are agents which destroy microorganisms and their spores. *Example:* Corrosive sublimate.

2. A *laxative* is an agent which increases or hastens the intestinal evacuation; it generally acts mildly, and without causing irritation. Its action is due to a slight stimulation of the peristalsis of the intestine.

3. The alkaloids of nux vomica are: Strychnine, and brucine.

4. *Properties of chloroform:* It is a colorless, volatile liquid, with a sweetish taste and a strong, peculiar odor. It is a good solvent for many substances not soluble in water. It is heavy, diffusible, of a neutral reaction, is not inflammable, freely soluble in alcohol and ether, but only in about 200 volumes of water.

Preparations of chloroform: Aqua chloroformi, emulsion chloroformi, spiritus chloroformi, linimentum chloroformi.

5. *Chemical incompatibility* may give rise to: The production of chemical substances not desired by the prescriber; the production of effervescence or explosion or some other process not desired by the prescriber; evolution of gases, changes of color, formation of precipitates; deposit of some strong and lethal preparation whereby a patient's life is endangered; the destruction of the action of a potent ingredient in a medicine by oxidation, reduction, or hydrolysis.

6. *Digitalis* is the dried leaves of *Digitalis purpurea*, the purple foxglove. *Symptoms of poisoning by digitalis:* "Nausea, and occasionally vomiting. Sometimes colic and diarrhea. After two or three hours, marked diminution in the frequency of the pulse, which may fall to 40 or even 25. Dyspnea, attended by a sense of oppression in the chest and coldness of the extremities. Headache, vertigo, and tendency to sleep. Usually attacks of syncope occur, provoked sometimes by the slightest movement of the patient. Death is generally by syncope, sometimes after several hours of coma succeeded by convulsions."—(Witthaus's *Essentials of Chemistry.*)

7. ERGOT. *Source:* The sclerotium of claviceps purpurea. *Physiological action:* Ergot stimulates and causes contraction of involuntary muscle fibers, hence it is a vasoconstrictor, hemostatic, and oxytocic. It is also a cardiac sedative; it raises the blood pressure, it increases peristalsis, and is an emmenagogue.

8. MERCURY. (1) Hydrargyri chloridum mite (calomel) dose gr. ss to x; used in syphilis, as a laxative or purgative, in congested or cirrhotic liver, in diarrhea, and as a diuretic. It is a heavy, white powder; amorphous; tasteless and odorless; it is insoluble in cold water and in alcohol, and very slightly soluble in boiling water; when exposed to the light it becomes discolored (first yellow, then gray) and partially decomposed; it sublimes without fusing. (2) Hydrargyri chloridum corrosivum (corrosive sublimate), dose gr. 1/60 to 1/30; used as an antiseptic, disinfectant, antiparasiticide, in syphilis, interstitial nephritis. It occurs as heavy, colorless crystals, with sharp and metallic taste, and acid reaction; it is soluble in 16 parts of cold water, and 2 of boiling water. (3) Liquor arseni et hydrargyri iodidi (Donovan's solution), dose ♏v; used as an alterative. (4) Hydrargyrum cum creta (gray powder), dose gr. ss to x; used in congenital syphilis, diarrhea of children, as a cathartic and diuretic, and in the beginning of fevers. It is a light gray powder, with a sweetish taste and no odor. (5) Hydrargyri iodidi rubrum, dose gr. 1/50 to 1/12; used in syphilis, rheumatism, and acute tonsillitis. It is a bright red powder and has neither taste nor odor; it is almost insoluble in water, but is freely soluble in solutions of potassium iodide. (6) Hydrargyrum ammoniatum, used as an ointment in 10 per cent. strength; employed for chronic skin diseases.

9. The *principal alkaloids of Papaver somniferum* are: Morphine, codeine, narceine, narcotine, thebaine, and papaverine.

10. *Sodium chloride* is emetic, purgative, and has osmotic power. *Sodium hydroxide* is irritant, caustic, and escharotic. *Potassium citrate* is diuretic, diaphoretic, and increases the alkalinity of the blood. *Adeps lanæ hydrosus* is emollient. *Epinephrin* is cardiac stimulant, vasoconstrictor, and raises blood pressure. *Fel bovis* is a cholagogue. *Ferri carbonas* is a hematinic.

THERAPEUTICS.

1. *Quinine* destroys the parasites of malaria. *Methylene blue* destroys the parasites of malaria. *Eucalyptus;* it is not known how this acts, or if it has any action at all in malaria.

2. In *hemorrhages from mucous surfaces,* the following may be used: Cold, adrenalin, alum, tannic acid, ferric chloride, gelatin, calcium chloride, opium, and ergot (for uterine hemorrhage).

3. Alkaline diuretics should not be used in cystitis, if the urine is strongly ammoniacal, or in advanced cases of the disease.

4. *To stimulate the heart:* Strychnine, atropine, and morphine. *To produce emesis:* Apomorphine. *To control hemorrhage:* Adrenalin.

5. The *treatment of pneumonia* "depends entirely on the type of case, and the condition of the patient. Routine treatment is the worst of all treatments. Answer the following questions before prescribing: Is the patient full-blooded, and is there a full bounding pulse? Is the pulse feeble, irregular, or intermittent?

"In the first case, in a young and previously healthy adult, if there be cyanosis, or signs of dilatation of the right heart, blood-letting to the extent of a few ounces may perhaps relieve the strain, but more generally treatment should be directed to maintaining the strength from the outset.

"In the latter case we can hope for nothing from a depressing treatment, so stimulants must be resorted to, such as alcohol, ammonium carbonate, egg and brandy mixture, quinine, ether, etc. The giving or withholding of alcohol depends upon its effect upon the pulse; should the pulse rate fall and the tongue become moist it may be continued. In asthenic cases, strychnine hypodermically is necessary from the outset, and normal saline may be given by the rectum or by the skin. Oxygen inhalations are used where there is cyanosis, but it is doubtful whether they have saved many lives. When there is evidence of failure of the heart (weakness of the second pulmonary sound, etc.) digitalis should be resorted to. Many prescribe it from the outset.

"The diet should consist of milk, beef-tea or broths,

white of egg, and so on. The patient should be as little moved as possible, and the bed-pan must be used. As in other fevers, an airy room and good nursing are essential.

"Remember that narcotics are not well borne in respiratory embarrassment as a rule. Chloral should be avoided, but *if pain be excessive* a hypodermic injection of morphine does *more good* than harm, notwithstanding that theoretically morphine is contraindicated. It should not be given later than the first few days of the illness. The pain may also be relieved by poultices, which, however, are of doubtful use if carelessly made, or by application of ice. Cold packs applied to the trunk only, and frequently repeated, are very useful in relieving both pain and fever. Depressant antipyretics are to be avoided.

"The results of *serum treatment* are not unequivocally encouraging, but vaccine treatment would seem to be of better promise. Where possible, an autogenous vaccine should be used." (Wheeler and Jack's *Handbook of Medicine*).

6. Belladonna will arrest the secretion of milk. The belladonna plaster is generally applied to the breasts; or the belladonna ointment may be smeared over the breasts.

7. *Therapeutic uses of glycerin:* As an emollient, laxative, and as a vehicle for other medicaments; it is sometimes given for hepatic and nephritic calculi, for trichinosis, and in vomiting of pregnancy.

8. *Therapeutic indications for use of chloral:* As a hypnotic (in absence of pain); as an antiseptic; in cases of acute mania or delirium tremens; in nervous dyspepsia; in fevers with high temperature, excitement, restlessness, etc.; in seasickness; in tedious labor, to relax a rigid os, and for uterine inertia; for nocturnal epilepsy; for infantile convulsions, chorea, whooping cough, and laryngysmus stridulus; in tetanus and strychnine poisoning it is said to be antagonistic; as an antipruritic.

Dangers are: Deep sleep, muscular relaxation, lowering of body temperature, lessening of sensibility and of reflexes, and the formation of a habit.

9. *Potassium bicarbonate*, taken on an empty stomach, enters the blood unchanged, meets the neutral phosphate of sodium and is decomposed, acid phosphate of sodium being formed which renders the urine more acid. On a full stomach it is decomposed by the acids of the gastric juice, increases the alkalinity of the blood, and makes the urine less acid. (From Potter's *Therapeutics*, etc.)

10. *Therapeutic uses of tartar emetic:* Emetic, cardiac depressant, in bronchitis, as an expectorant, a diaphoretic; not much used now.

PATHOLOGY.

1. The urine of patients affected with autointoxication may show either (1) the presence of acetone, diacetic acid, and beta oxybutyric acid; or (2) the presence of an excessive amount of indican.

2. A *persistent low blood pressure is found* in: Many acute infectious diseases, anemia, cachectic conditions, and shock.

3. *Arterioselerosis is found* in: Gout, syphilis, chronic nephritis, alcoholism, lead poisoning, rheumatism, overeating, excessive muscular work, emphysema, cirrhosis of the liver. It *predisposes* to: Monoplegia, hemiplegia, apoplexy, interstitial nephritis, myocarditis, thrombosis, embolism, gangrene.

4. *Absence of chlorides in the urine may indicate:* Starvation, lobar pneumonia; they are *diminished* in many of the acute fevers, anemia, cachectic and malignant conditions, extreme diarrhea and when large effusions are present.

5. *"Epithelioma,* or squamous-celled carcinoma, may arise on any surface covered with stratified epithelium. It usually arises in the middle-aged or elderly, but may also occur in the young. It often results from long-continued irritation, and may arise in old scars or ulcers. It may appear in one of three forms: (1) A wart-like growth with an indurated base; (2) a small circular ulcer with raised, rampart-like edges; (3) an indurated fissure. The growth extends to the deeper structures; the surface ulcerates and becomes foul from contamination with putrefactive organisms. The nearest lymphatic glands always become infected sooner or later, and a fatal termination occurs rapidly unless treatment is early and thorough. Secondary deposits, except in the glands, are rarer than in glandular carcinoma. The glands sometimes undergo cystic change, invade the skin, ulcerate, become foul, and may cause death by secondary hemorrhage from ulceration into large blood vessels. Microscopically, columns of cells are seen extending from the epithelium into the underlying tissues, and interlacing with one another. In some of the columns concentrically arranged masses of flattened, cornified cells may occur; these are called 'cell nests.' The tissues immediately surrounding the new growth are infiltrated with small round cells." (*Aids to Surgery.*)

6. *Formation of pus:* "When pyogenic bacteria are introduced into the tissues there ensues an inflammatory reaction, which is characterized by dilatation of the blood-vessels, exudation of serum, migration of large numbers of leucocytes, and proliferation of connective tissue cells. These wandering cells soon accumulate around the focus of infection, and form a protective barrier which tends to prevent the spread of the organisms and to restrict their field of action. Within the area thus circumscribed the struggle between the bacteria and the phagocytes takes place, and in the process toxins are formed by the organisms, a certain number of the leucocytes succumb, and, becoming disintegrated, set free certain proteolytic enzymes or ferments. The toxins cause coagulation necrosis of the tissue cells with which they come in contact, the ferments liquefy the exudate and other albuminous substances, and in this way pus is formed." (Thomson and Miles' *Manual of Surgery*).

7. *Leucemia* is a condition in which there is a great and persistent increase in the number of white blood corpuscles. There are two varieties of the disease: (1) *Splenomedullary* in which the chief changes are found in the spleen and bone marrow; and (2) *lymphatic*, in which the most marked changes are observed in the lymphatic glands.

It is possible for leucemia to be confounded with splenic anemia and Hodgkin's disease. The diagnosis is made by an examination of the blood. In Hodgkin's disease there is either no increase in the number of the leucocytes, or a very slight increase. In *anemia*, there is a marked diminution in the number of the red blood corpuscles and there is no leucocytosis. In *splenomedullary leucemia*, there is an enormous leucocytosis, and myelocytes are present. In *lymphatic leucemia*, the lymphocytes form the main part of the leucocytosis, and there are no myelocytes. The disease is of gradual onset, and may be accompanied by weakness, palpitation, dyspnea, and dyspepsia; the face is pale or sallow; the spleen or lymphatic glands will be found enlarged; fever and dropsy may occur later in the disease; the abdomen is generally swollen and emaciation is observed; the urine is high-colored, scanty and may be albuminous.

8. *Chronic infections of nose, throat, and teeth may induce:* Periostitis, ostitis, caries, and necrosis of the neighboring bones, thrombosis of the cavernous sinus, and even so serious a condition as intracranial abscess; infection of bones at a distance and polyarthritis may also occur.

9. *Vertigo* may indicate: Neurasthenia, congestion or anemia of the brain, eyestrain, disease of the internal ear, meningitis, tumor of cerebrum or cerebellum, gout, indigestion, heart disease, arteriosclerosis, autointoxication. It may also be caused by certain drugs.

10. The secondary symptoms of syphilis appear at about the end of the 45th to the 90th day; the tertiary symptoms begin at about the end of the second year. Nocturnal headaches in syphilis are suggestive of cerebral syphilis.

(*To be continued.*)

Disturbances of Ossification in Endemic Cretinism and Goiter.—Wegelin believes that in countries in which goiter is endemic, a distinct arrest of ossification is noticeable even in the fetal period, this phenomenon being attributable to hypothyreosis, and expressed as a lack of bone nuclei in the inferior epiphysis of the femur in the newly born. This intrauterine arrest of development is an inversion of conditions when there is hyperthyroidism of the maternal organism. Thus when gravid animals are fed with thyroid substance, the litter is less numerous while the individual young are better developed. In fowls thyroid feeding cause not only larger eggs but more eggs, while after thyroidectomy these results are reversed. This law justifies the systematic wholesale use of thyroid feeding for cretins and cretinoids.—*Correspondenz-Blatt für Schweizer Aerzte.*

RADIUM EFFICIENCY IN NON-MALIGNANT SURGICAL CONDITIONS.*

BY ROBERT ABBE, M.D.,

NEW YORK,

SENIOR SURGEON, ST. LUKE'S HOSPITAL.

IT will refresh our minds to divert attention from the popular hue and cry after a cancer cure by radium, by considering a few of the interesting list of non-malignant troubles which this remarkable agent has helped. It will be consistent with the aim of this most practical society that its members should be informed on practical results.

One interesting demonstration of the prompt curative action of radium and its permanent benefit is in *vernal catarrh*, in a disease considered intractable by oculists, as well as physicians. This affection of the eyelids is a conjunctivitis recurring each spring, and often lasting through the year when it has become established. The lids are hot, swollen, red, and itchy. Photophobia often compels the patient to stay in a semi-dark room. The lids gum up and are glued together in the mornings with a sticky, often mattery secretion. On everting the upper lid there is seen a mass of granulation tissue standing far out from the under surface, and often grouped in bunches. This condition does not occur in the sulcus above the cartilage of the lid. By this it can be differentiated from trachoma.

I have treated in all ten cases which were recurrent for many years and can assert that the

FIG. 1.—Typical vernal catarrh; this inveterate case had resisted every variety of scientific treatment by specialists, but was cured by radium.

improvement always begins soon after the first treatment. Most cases had had extreme treatment by slicing off the masses, cauterization, and caustics before I saw them, and had become the *bêtes noires* of the oculists.

A uniform benefit and ultimate cure follow the judicious use of radium. Technically, a fifteen

FIG. 2.—Best method of exposing the under surface of the eyelid to strong radium; this is placed in a groove at the end of a long lead cylinder covered by a celluloid holder. The cornea is protected by the lead beneath the groove holding the radium tube.

minute application of a tube of strong radium under the eyelid, moved back and forth, with a lead device to protect the cornea, repeated every month or two, constitutes the simple and rapidly helpful method. With a drop of cocaine, the most sensitive eye feels no pain. The cases I have so treated have now remained cured up to ten years, as shown in the case to-night. The method of its action is specific, in altering the hypertrophied cells of the mucous surface, which have made a veritable tumor structure.

The second interesting condition in which radium has no rival is in reducing *lymphoid tumor* tissue such as is found in tumors of the tongue called hemolymphangioma, and in other parts of the body. I have reported a series of these in a paper read before the American Surgical Association last spring, and will not even quote further from it here, but merely say that it is a triumph in a small group of formerly hopeless cases. Its selective action on the lymphoid cell growth is emphatically specific.

This overgrowth of one element of skin structure in the scheme of tumor formation is not unlike papillary warty growths which subside, like all *vocal cord papillomas* as you have seen to-night in the brilliant and permanent restoration of voice with perfect vocal cords five years after apparently hopeless conditions.

Warts, in places delicate as the edge of the eyelid, or the tender vermilion of a child's lip, or the coarse skin of the sole of the foot, or under the finger nails, or in the scalp, where scars are not desirable, radium has cured for me a hundred times

*Read at a meeting of the New York Clinical Society, April, 28, 1916.

with usually no scar. I would class this with specific action inasmuch as a retrograde of wrong-growing cells takes place after this atomic bombardment, causing them to return to normal growth.

Leucoplakia, considered as a simple overgrowth of surface cells of the tongue or mucosa lining the cheeks is not unlike the keratosis of the skin, heaping up in places and making a veritable new growth, often precancerous and tending to extend downward and become a cancerous invasion. This is seemingly as capable of cure by radium within the mouth as it is in skin hyperkeratosis, whose disappearance can be predicted with as much certainty as the treatment is easy. In the mouth, however, the time and method of application require much more judgment and skill to attain good results. It is associated with a transient painful irritation which is essential to success. We face the fact, however, that before radium was available no cure was known. Mr. Butlin once told me that "if radium would cure leucoplakia, it would do what neither cutting out, or shaving off, or caustics, or cautery had ever done in his hands."

An allied condition of the lips presents another phase of the successful use of this energetic agent. There is occasionally seen a weak spot of the skin

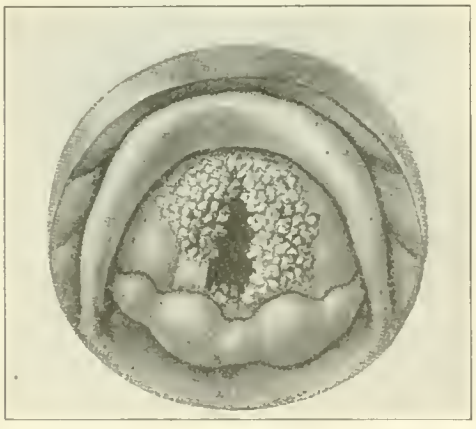

Fig. 3.—This patient with papilloma of the larynx remains perfectly cured after one radium application, and sang with perfect voice five years after the treatment.

of the lip, a chronic thin surface ulcer or abrasion. The skin refuses to heal, or if it heals with a thin surface, it quickly breaks down and a *chronic abraded ulcer* remains, not with cut-out edges, but, as ice freezes, with a thin blue edge always looking as if it might heal. There seems in these cases to be a lack of force in the epithelial cells at the edge. It often lasts for years, and is in striking contrast to the hypertrophic conditions on the lip, both of which I illustrate, and both are equally well cured by radium. The same is true of the chronic painful crack of the lip.

It seems paradoxical that the same agent can cure an overgrowth keratosis and a deficient growth, as in these abrasions, and until we know why cells grow, we may not explain it. Some satisfaction, however, may be had in a hypothesis which I offered some years ago which argues backward from the known output of beta radiation of radium, an enormous charge of negative electron particles driven into the disorderly growing cells. Inasmuch as there follows a retrograde change in the overgrown cells, it must be due to something supplied to them by this treatment. If, hypothetically, we surmise that the vital force actuating a normal cell growth, is a balance of electric action established within it, and we conjecture that a riotous overgrowth may be due to loss of balance, may it not be that the preponderance of positive or negative charge is responsible for the disturbance which is corrected by the new supply of nascent negative electrons. Sci-

Fig. 4.—Chronic abraded ulcer of the lip.

ence is about ready to concede that the actuating force of nerve and cell activity is electrical, and singularly enough this new agent is almost wholly a discharge of material particles each bearing a charge of electricity, some positive and some negative. It is not easy to explain, for instance, the recovery of the destructive myeloid tumor of the jaw, which I showed you to-night, as a fortuitous reassembling of disordered cells to orderly rearrangement to form a normal jaw again which has endured for twelve years. This I would designate

Fig. 5.—Small typical true keloid of the chest; it had been once cut out, and returned, as they all do, before coming to me for radium treatment. This cured it with a smooth skin scarcely depressed.

specific action. In what the specific action consists, we can only speculate.

By contrast, there is an action of radium which is curative by irritation only, as in *nevus.* The endothelium of veins or arteries undergoes hyper-

plasia and partly or wholly obliterates the lumen, so as to induce a gentle fibrosis and cure of the birthmark. Patience and discretion are needed to keep a velvety skin and not produce a cicatricial atrophy from overtreatment.

FIG. 6.—Extensive keloids following two years after an acid burn.

The active irritation of these intense penetrating rays is absolutely necessary to a successful result, in any of its many uses. This provokes a kind of inflammation, except that it has no bacterial origin. Especially noticeable is this in *keloids*, one of the most useful fields of its work. It was Wickham of Paris in his early work who first showed me cases of keloid cured by radium, and told me there was no difference between so-called true and false keloid; both were equally easy to cure. I have verified this in a great number of patients. Cases which no surgeon would dare cut out are perfectly cured by inducing, first, a sharp radium inflammation which transforms the hard keloid masses of cells and fibrous tissue. This is followed by an atrophy of the mass as the inflammation of the fourth week subsides. This is especially grateful in the so-called true keloids of the front of the chest, often seen in young women, which recur with terrifying certainty when cut out, but which invariably leave a thin, flexible cicatrix after radiumizing properly.

In the terrible case of face keloid from acid burns, which you have seen to-night, the condition two years after the accident was one of progressive very dense hard masses much as if leather were drawn tight over a golf ball. Several sharp radiumizations were induced in all, and each was followed by marked softening and atrophy until now they are all soft and pale and nearly flat.

But I come at last to speak of the most extraordinary of all the remarkable effects of radium known to me—its cure of the disease known as *uterine fibroids*. It is fair to call this a disease by itself because it has no exact counterpart that I know of, in the body. It is essentially a tendency of the muscular structure of the uterus to grow tumors made up of the same muscle structure. One, or many, they are myomata; some old and fibrosed, some young and of juicy cell structure. Those growing close beneath the lining membrane of the cavity usually induce severe hemorrhages, often very grave. For forty years surgery has had but one answer to the appealing sufferer—"Cut them out, usually with the whole uterus also." It would be difficult to compute the hundreds of thousands so treated in the hospitals of the world.

The surgical results must include not only a great majority of satisfactory cures, but also deaths by hundreds from operative risks and the several sequels of pelvic abscess, abdominal wall abscess, hernia of the scar, cystitis from catheterization, femoral phlebitis, and so on. Add to this the four or six weeks of hospital care—which in private means often a continual surgical attendance of many weeks more, where the patient is often more frail. The absence from work or home duties, in women who can ill spend the time, completes a long list of essential incidents associated with the customary surgery of uterine fibroids.

Let us imagine, now, that a remedy for all this is found in so simple a treatment as the introduction of a small tube of radium into the uterine cavity, without ether, for two hours on two or three occasions, without entering a hospital, and that, following this, the excessive hemorrhage stops and the tumors progressively shrink until they disappear. Is this possible? It is not only possible, but has come to the point of complete demonstration. Accumulated cases now show that it may be depended on for permanent cure, with apparently no risks, no delay, no hospital, small cost to the patient

FIG. 7.—Same patient as shown in Fig. 6, after radium treatment.

in time and money; and to the surgeon, small cost of time. It sounds like a Münchausen tale. It is one of the most beneficent actions of this unique agent.

My experience with it dates back to 1905, which is the first case as far as I know in which it was used to arrest a hemorrhage and for its hoped for good effect on the tumor. That and another which followed soon after were recorded by me in 1906, and have been watched ever since. The tumors shrank year after year until they remained but very small, inert buttons on the uterus. Since then I have applied it in more than thirty cases and have yet to see a case which did not shrink, some completely, some rapidly—all in large measure. It may truly be called a specific for uterine fibroids, and must supplant operative treatment as fast as conviction and the accession of radium come to operators.

Its special value shows in the many cases of violent hemorrhages from fibroid disease. Here the uterine lining is overgrown and highly vascular, or stretched out thin and bleeding from open mouthed veins. The contact of radium with these blood vessels seals them up by occlusive inflammation, due to

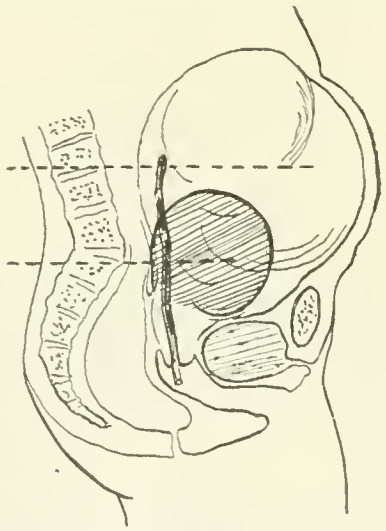

FIG. 8.—To illustrate the action of radium on a large uterine fibroid. *A*, tumor before the application of radium; *B*, tumor ten months later.

the active beta rays, while the penetrating gamma rays go through the whole disordered cell mass, and produce a retrograde change in the conduct of each cell so that it begins its retreat at once, and the growth's shrinkage is measurable in from two to six months.

The very large tumor in a desperate case of hemorrhage, published by me last June, has shrunk from a diameter of ten inches to four, in ten months, and will disappear probably within a year. Meanwhile the exhausting hemorrhages ceased in six weeks and have never recurred. The patient has enjoyed perfect health since. This may be said of all the cases treated.

One patient whom I have shown you to-night with the most extensive *lupus erythematosus* of the entire face, ears, and side of the neck, and of his hands, was cured by one thorough radium treatment. This case does not stand alone.

It is probable that every case will yield to proper radiumization, judging by five cases of this disease on the face which have yielded excellent results which seem permanent. The first case was of a man who had typical patches on both cheeks. He remained cured after my treatment in 1904.

Time has limited me in this paper to speaking of only a few of the non-cancerous cellular growths in which the action of this comparatively new agent—radium—has a character of its own.

13 WEST FIFTIETH STREET.

RADIUM IN THE FIELD OF LARYNGOLOGY.*

BY D. BRYSON DELAVAN, M.D.,

NEW YORK.

THE past year has brought distinct advances in the knowledge of the use of radium, in no department with more encouraging results than in ours. To-day many observers are studying its effects in an ever increasing variety of disorders, some of which are far beyond the limits of previous conjecture. Additions are being rapidly made to the number of conditions in which the treatment is effective, and substantial encouragement is being given to the hope that there has been found in radium a truly valuable therapeutic agent. Several of our institutions, notably the General Memorial Hospital, New York, have been fortunate in acquiring amounts of radium large enough to meet all of the probable demands of treatment, while those in whose hands it has been placed for administration are gaining experience in its application and learning how it may best be utilized and controlled.

Some contributions have been made to the literature of the subject in general, but in the department of the diseases of the upper air passages little has yet appeared. This is not surprising. The study of radium is in its infancy. Few investigators at present are ready to issue formal reports of their work, wisely refraining from announcing results until their deductions can be placed upon a stable basis of well proved fact. Any attempt to drag it before the medical public at the present time would be premature. What is needed is not publicity, but rather the development of scientifically proved data upon which, and only which, reliable reports of progress are possible. The securing of such data requires *long-continued and painstaking study of the action of radium, under conditions favorable for accurate observation, in the hands of men especially qualified for the work.* When these conditions have been fulfilled, and not until then, we may hope for the beginning of a literature at once valuable and instructive. Meanwhile, however, even the most conservative observers are willing to admit that encouraging progress is being made. Were the actual experiences of different institutions devoted to the study of radium to be quoted the truth of the above statement would be plain.

A few fragmentary contributions and reports have appeared, some of which are worthy of notice. From these it is again evident that the progress being made in the knowledge of radium efficiency in non-malignant surgical conditions and in certain nonsurgical affections of the upper air passages continues to be gratifying. This is shown by the work of various observers in the United States, particularly by that of Dr. Robert Abbe of New York, and by the reports of the two leading British institutions, the Radium Institute of London and the Royal Infirmary of Edinburgh.[1]

Thus the London Institute reports excellent re-

*Read before the American Laryngological Association at its thirty-eighth meeting, Washington, D. C., May 10, 1916.

sults in the treatment of "vernal catarrh," patients treated for it by radium having in a large proportion of cases been cured without recurrence, although under observation for a series of years.

In the treatment of nævus by radium remarkable results are being obtained.[2] The most brilliant of these are seen in young children where conditions of unusual severity in the vicinity of the lips and nose, far beyond the limits of surgical relief, are being successfully reduced.

Rhinoscleroma, according to Kahler,[3] has been treated with good effect. Good results have been claimed from the application of radium in goiter and in tubercular glands.[4] For the latter Bissell[5] of New York is particularly impressed with its value. Under his observation proper radium treatment has often and completely restored such glands to their normal functions. Abbe believes that leucoplakia of the tongue is not unlike a keratosis of the skin, often pre-cancerous and tending to extend downward and become cancerous. He considers that it is as capable of cure by radium as is the skin keratosis. Delavan[6] has called attention to the same thing. Serra[7] reports a successful case.

Much attention is also being given to the study of radium as applied to new growths in general and many highly interesting and important facts are being obtained. This is especially true of growths of a non-malignant character. In the treatment of nasopharyngeal fibroma the use of radium has proved encouraging, particularly so in view of its success in the treatment of fibromata in other parts of the body.[8] Abbe[2] has shown a case of myeloid tumor of the jaw, completely cured.

In the treatment of non-malignant intralaryngeal growths many highly interesting results have been obtained, tumors of various histological structures having disappeared, in a number of cases with complete restoration of the singing voice. The treatment of papilloma of the larynx by means of radium is one of the most interesting phases of its use. In view of the success already attained with it, as well as with warty growths in general, the outlook for it is most promising.

Weil[9] reports a parotid tumor (adeno-cystic-epithelioma) of seven years' standing, which was treated for six weeks by the insertion of radium into it. The growth disappeared, and at the end of two years has not recurred. Freudenthal[7] reports a case of fibrosarcoma of the right antrum cured. He also reports a case of sarcoma of the tonsil, in which the growth disappeared and remained in abeyance for six years. Then it recurred and the patient died. In another similar case the growth disappeared for six months.

In this highly specialized department, laryngology, radium promises to occupy a wide and important field.

While the treatment of these various lesions has been attended with interesting results, the final value of radium in certain of the more serious affections has yet to be proved. Especially is this true of its use in carcinoma, for while a considerable number of cases have been placed under treatment it has been claimed by some that the effect of radium has in certain instances been unsatisfactory; and even in some in which its influence has been temporarily beneficial the good effect has not always been lasting, or else too little time has elapsed to prove its final value. In a few cases it is said that not even temporary benefit has resulted, while in some of these the advance of the disease seems to have been hastened. Again, while parts of the region exposed have undoubtedly improved, other parts have retrogressed. Admitting that these several objections may contain more or less of truth it is, nevertheless, encouraging to know that the causes of more than one of them are understood and that diligent effort is being made to discover the means by which they may be prevented.

In this connection, recent British experience and opinion is interesting.

The report of the Radium Institute of London[1] states that "epithelioma of the buccal, lingual, and pharyngeal mucous membranes usually proves refractory and disappointing in its response to radium," but, it is significantly added, *"under new methods of application better results may be expected.* Thus far, the treatment does not seem to have much effect in arresting the disease."

The report of the Royal Infirmary[1] gives a far more sanguine outlook. Thus: "While in advanced malignant cases a cure may not have been effected, yet in practically all treated more or less benefit was produced, through the relief of pain, the cessation of discharges, the healing of ulcerative surfaces, the removal of local growths, and the prolongation of life.

"Malignant disease of the posterior nares, buccal cavity, pharynx, and larynx seems less amenable to radium, but this may be from the difficulty of administering a sufficient dose in such positions."

Several cases that have come under my own observation have shown effects worthy of notice. Two of them were epithelial carcinoma, originating in the left side of the throat close to the wall of the larynx and, as far as could be ascertained, extralaryngeal. Both patients were men in the early fifties, hitherto in perfect health, active, vigorous, and of excellent antecedents. When first seen, the disease in both had invaded the interior of the larynx, the left lateral wall of the pharynx, the pyriform sinus, the tonsil, and the base of the tongue. In both, ulceration was present and there was marked aphonia and dysphagia. Operation was impossible. Both were subjected to the radium treatment at the same institution and large doses were applied. In both the results have been materially the same.

The first effect of the radium locally was an almost immediate control of the secretions of the throat. From having been abundant and fetid they promptly ceased. Following this the areas of ulceration rapidly diminished in extent, and in the less severe of the two cases they disappeared; while in the other case they seemed to do so, although it has not been possible to prove this owing to the difficulty of examination. The swellings which had appeared over extensive areas of the affected parts decreased markedly, and the infiltrated tissues were reduced in size, became soft to the touch and more natural in appearance. Accompanying these changes extraordinary improvement took place in the various functions of the throat. Thus, the voice became clearer, and deglutition, which before the application of radium had become almost impossible, showed such improvement that both patients were able to swallow without pain and to largely increase the variety of their food.

Together with these local changes, the improvement in general was remarkable. Digestion became normal and sleep more prolonged and restful; while with the improved nutrition a steady increase of strength was apparent and a rapid return

to an almost normal condition of good spirits. One of these patients, a physician, was able to resume his office practice and for two months remained steadily at work.

These patients, as well as all who have seen them, admit that even if from now on the progress of the disease should ultimately be unfavorable the benefit already gained in the relief of suffering and the added comfort afforded, would well repay them for any inconvenience the radium had caused. This is an important concession, for the superficial burn sometimes resulting from radium may be an unpleasant feature. Compared, however, with the results of any serious surgical operation, it is but a slight annoyance. And yet how gladly will the patient submit himself to the knife and to weeks and perhaps months of disability and suffering following its use for the sake of cure, quickly forgetting all the harrowing details of his surgical experience and even its resulting mutilations in the joy of being restored to life and health! Any method which will cure carcinoma, at the same time leaving the normal parts intact, with no worse penalty than a slight superficial burn, should surely be welcomed with acclaim.

The present is no time for the adverse criticism of radium. The study of the radium treatment of carcinoma is but just begun. Some, at the very threshold, are already discouraged, and are announcing themselves as unwilling to believe in its efficacy. To these we may repeat that the knowledge of the use of radium in general is still in embryo.

The failure to gain uniformly reliable results in carcinoma is due to our imperfect knowledge of the methods by which the radiations can be controlled, of the amounts of radium which should be used, and of the correct duration of the exposures. The all-important basic principle has certainly been proved, namely that, under proper application, *radium will destroy a superficially located cancer cell.* Granting this proposition, it is by no means impossible that with increased knowledge of its action, and skill in its application, deeply seated cells may be successfully reached and destroyed, while at the same time the surrounding tissues are effectively protected.

Already, results worthy of profound consideration have been obtained. Far from being discouraged, there is every reason why persistent and continued effort should be made to finally solve the existing problems and give to the world a cure for one of its most grevious scourges. Fortunately, there are some who, in the face of many difficulties are earnestly and hopefully striving to obtain this end. Let such gain inspiration from Trudeau[11] that noblest of humanitarians: "Optimism is a mixture of faith and imagination, and from it springs the vision which leads one from the beaten paths, urges him to effort when obstacles block his way, and carries him finally to achievement when pessimism can only see failure ahead. Optimism may, and often does, point to a road that is hard to travel, or to one that leads nowhere; but pessimism leads to no road at all. * * *

"Let us not therefore quench the faith nor turn from the vision which, whether we own it or not, we carry * * * and thus inspired many will reach the goal," as have all whose hopeful imaginings and courageous efforts have been the basis of every noble success the world has ever seen.

FRACTURES IN CHILDREN.

BY JACOB GROSSMAN, M.D.,

NEW YORK.

FRACTURES in children vary from those in adults not only in severity and variety, but also in their management. The bones in children are soft and elastic, they have in their ends cartilaginous discs which give way to traction and bending. Where in adults an injury will produce a dislocation, this same injury in children will usually produce a fracture. The degree or severity of the injury bears very little relation in the production of fracture in a certain percentage of children. At times a mild trauma as falling on the floor and striking upon the affected part or a slight knock against a chair will produce a fracture. Occasionally a severe trauma such as falling down a flight of stairs, will not produce more than an injury to the soft parts or an injury which is very often overlooked, namely, intraperiosteal fractures.

A great many fractures seen by the orthopedic surgeon are fractures which are overlooked and are often diagnosed as "sprains," contusions, "twisted tendons," etc. The absence of the cardinal signs of fracture, *i.e.*, crepitus, false mobility, deformity, and ecchymosis probably accounts for the mistakes in diagnosis. The absence of these signs can be accounted for in one of the following ways:

1. An impaction of the fragments may be present.
2. One fragment may be too small or too firmly attached to the neighboring structures.
3. Finally the fracture may be an incomplete one, being of the fissure or torsion variety.

It is this latter cause of error which is commonly found in the care of children. These fractures are incomplete and are known as subperiosteal or intraperiosteal fractures. The most constant and what can almost be called diagnostic sign, is the localized bone or "pencil tenderness." The way to map out this localized or pencil tenderness is to palpate or make pressure with the back of a pen or the rubber tip of a lead pencil. By tracing the point of maximum tenderness one can in a vast majority of the cases trace the line of fracture, besides making the diagnosis. We have confirmed our clinical findings by means of Roentgen ray pictures, a few of which will be found elsewhere in this paper. Although there is general pain in cases of fracture, still firm pressure about the seat of injury will, in a vast majority of cases, reveal a definite, constant point or line of pencil tenderness over the fracture. This tenderness is at times very exquisite. Many parents are surprised to learn that their children had sustained fractures, so trivial had been the suffering, both subjectively and functionally. The diagnosis in these cases was made by tracing the line of pencil tenderness. The duration

of this sign varies, sometimes persisting for weeks. At a recent meeting of the Alumnæ Society of Lebanon Hospital, the writer demonstrated several cases of intraperiosteal fractures, all diagnosed by tracing the line of pencil tenderness and all confirmed by subsequent Roentgen ray pictures. The complete reports of these cases follow.

Fig. 1.—Case I. Fissure fracture of the tibia.

Case I.—Dorothy E., five years of age. A few days before coming to the Lebanon Hospital Orthopedic Clinic, the child tripped and fell down the stairs, a distance of a few steps. The mother thought nothing of the injury as the child was able to get about. She applied home remedies with very little success. For the following few days the child complained of having pain only when she walked. It was on account of this pain that the patient was brought to us.

Examination: The child walked with a slight limp on the left side. The left leg was slightly swollen, there was no deformity or ecchymosis. Crepitus and false mobility were also absent. A line of maximum tenderness was traced along the shaft of the left tibia for a distance of three inches. A diagnosis of an intraperiosteal fracture of the tibia was made and proper treatment instituted. The mother could not understand how it was possible for the child to have a fracture and still be able to get about. A subsequent Roentgen ray picture showed an intraperiosteal fracture of the tibia, corresponding to the line of pencil tenderness, which we had traced. Fig. 1 is an *x-ray* picture of this case, showing the location and type of fracture.

Case II.—Sarah S., nineteen months of age. A few days before coming to our clinic, the baby fell out of her carriage, striking upon her left leg. After the accident the child was unable to walk, and was very tender at the site of the injury. She was brought to us on that account.

Examination: The child was unable to bear any weight on her left lower extremity. There were slight ecchymosis and swelling over the site of injury. Crepitus, false mobility and deformity were absent. A line of maximum tenderness was traced along the shaft of the lift fibula for a distance of two inches.

A diagnosis of an intraperiosteal fracture of the fibula was made. A subsequent Roentgen ray picture confirmed our diagnosis. (Fig. 2.)

Case III.—C. H., three years of age. One week prior to his visit to our clinic the child fell, striking upon his right forearm. The mother thought that the child had only bruised its forearm, hence the delayed visit to our clinic.

Examination: The child refused to move his right arm. There was slight swelling and ecchymosis over the palmar surface of the right forearm. Crepitus, deformity and false mobility were absent. A line of maximum tenderness was traced running transversely over the lower end of the radius, about one inch above the articular surface.

A diagnosis of greenstick fracture of the radius was made and a subsequent Roentgen ray picture (Fig. 3) confirmed our diagnosis.

Fig. 2.—Case II. Fissure fracture of the fibula; another photograph, taken in a different plane was negative. This shows the importance of taking Roentgen-ray pictures in more than one plane.

The treatment of this type of fractures is the same employed in complete fractures, differing only in having a shorter period of immobilization.

Many authors report loosening or separation of the epiphysis as a common occurrence in children. In our series there were just two cases or about 1 per cent. of epiphyseal separation. In these cases both were at the lower end of the radius, the result of a severe trauma. In a vast majority of these so-called epiphyseal separation cases, were Roentgen ray pictures to be taken a fracture just above the epiphyseal line would be revealed.

Fig. 3.—Case III. Greenstick fracture of the lower end of the right radius.

These peculiarities of the bones in children make

the diagnosis quite difficult, especially in intraperiosteal fractures, when one looks to make a diagnosis on the cardinal signs of fracture. We must always think of fracture as a possibility when children refuse for any length of time to use a

FIG. 4.—Case IV. Figure of eight dressing for fracture of the clavicle.

limb, especially if they do not use it when their attention is distracted from it or when they are at play. Many cases diagnosed as contusions, twisted tendons, or bad sprains eventually turn out to be fractures. In this series fully twenty-five per cent. of them were treated as sprains, twisted tendons and contusions.

In general the treatment of fractures in children is much simpler and easier than it is in adults. The thick periosteum which is usually partially intact prevents any considerable dislocations, nor are the muscular tractions quite as strong and are easier overcome than in adults. The tendency to heal is much more intense in children and hence the time of union is much shorter, and immobilization is of shorter duration than that of the adult. An exception to this is found in rachitic children, where on account of the pathological condition in the bones, there is interference with the healing process and hence it takes a longer time for the fracture to unite.

The scar which forms is usually a soft one and only becomes solid when the rickets is cured. In this type of cases a slight push, a jump or even a sudden strong contraction of a muscle will suffice to break completely a bone which is already bent. This is also true in any process which softens the bones, *i. e.*, osteomalacia, atrophy of the bone through disuse (as in paralyses and inflammations), and in osteogenesis imperfecta in which condition the bones are very brittle.

This paper is based on the study of 200 cases of fractures, divided as follows: Fracture of the clavicle, 50. Fracture of the humerus, 48; (*a*) surgical neck, 3; (*b*) shaft, 5; (*c*) lower end, 40. Fractures of the forearm, 92; (*a*) shaft of the radius, 20; (*b*) shaft of the ulna, 5; (*c*) olecranon, 3; (*d*) both bones, 24; (*e*) lower end of the radius, 40. Fractures of the leg, 10; (*a*) tibia, 5; (*b*) fibula, 5. There were 130 in males and 70 in females. The ages were between fourteen days to eleven years. The cause in the majority of the cases was a direct injury.

Fracture of the Clavicle.—This was a fairly frequent fracture in the series of cases, there being 50 cases, or 25 per cent. The common cause was a fall upon the shoulder and the common site was at the junction of the middle and outer third of the bone. Some of the cases were incomplete, being of the intraperiosteal variety, with no displacement of the fragments. The diagnoses in these cases were made by tracing the maximum point of tenderness. The remainder were complete and were accompanied by severe pain and a lowering of the shoulder. The pain was especially evident when the arm was abducted above the horizontal position. Deformity, crepitus, false mobility, and marked tenderness were all present.

Treatment: In treating fractures in infancy and childhood one must always remember the differences between the infant, the child, and the adult. The tender skin of the infant, its round, agile body, the movable cover of fat which envelopes the soft bones offer considerable difficulty to an exact therapy.

In fractures of the clavicle the dressings at our disposal are (*a*) the figure of eight bandage and (*b*) adhesive plaster.

Figure of eight bandage: Before applying the bandage it is very important to subject the axillæ to preliminary treatment. This consists in dusting them with boric-acid powder and the insertion of a pad of boric-acid lint in each to absorb the perspiration and keep them dry. The deformity when present is then reduced and the fragments are retained in their proper position by an assistant. A flannel bandage about two inches wide is then applied in a figure-of-eight manner so that the figure-of-eight is behind and the shoulders are held back by the two loops of the eight. The forearm is then supported by a sling about the neck.

Fig. 4 shows the back view of this dressing.

CASE IV.—Josephine B., four years of age, fell and struck her right shoulder a few days before coming to our clinic. This accident was followed by severe pain and disability.

Examination revealed a complete fracture of the clavicle at the junction of the middle and outer third

FIG. 5.—Case V. Fracture of the upper part of the humerus.

of the bone. The outer fragment was displaced downwards accompanied by the shoulder and the inner fragment was displaced upwards. There was complete disability, attempts at passive abduction being accompanied by severe pain.

Adhesive plaster dressing: After the preliminary preparation of the axillæ a strip of adhesive plaster about one and a half inches wide and about seven inches long is applied, starting in front of the affected shoulder, continued outward around

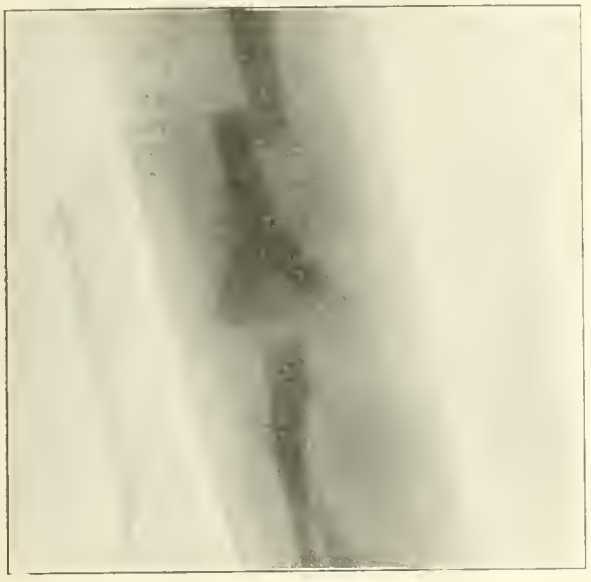

Fig. 6.—Case VI. Fracture of the shaft of the humerus.

the shoulder and then backward and downward over a pad (which is placed between the scapulæ) to the opposite anterior axillary line. It is important to make traction on the affected shoulder and draw it backward while this strip of plaster is being applied. A second strip of plaster, about the same width and length, is then applied, starting from the middle of the arm on the affected side (not completely encircling it) and continued backward (drawing the arm back) to the anterior axillary line on the opposite side. The wrist on the affected side is to be supported in a sling about the neck.

The advantages of this dressing are: (*a*) Its simplicity; (*b*) we can always have the parts under observation without removing the dressing; (*c*) there is very little danger of compressing the blood vessels or nerves.

The dressings are usually retained for a period of ten days, when they are removed and after-treatment is begun. This consisted of massage and passive movements of the shoulder. After a few days active movements and exercises are begun.

In infants and younger children we usually employed the figure-of-eight dressing. In older children it is a good plan to use the adhesive plaster dressing previously described. The time of union in all the cases averaged about two weeks. There were practically no deformities or complications.

The adhesive plaster dressing was advocated by Dr. S. Kleinberg of this city.

Fractures of the Humerus.—Fractures at the upper end.

Of these we had three cases, all fractures of the surgical neck of the humerus. The cause was a fall upon the shoulder. In treating this type of fracture one must always bear in mind that the loss of abduction interferes most seriously with the function of the joint. Hence we have treated these cases with the arm in abduction and retained it there by means of a plaster of paris bandage spica. The spica was removed after three weeks and the patients were discharged after a few days after-treatment, after which time abduction, adduction, and rotation were free and painless. The following is a report of one of these cases:

Case V.—Yetta G., four years of age. Eight days before coming to our clinic, the patient fell, injuring her right shoulder. She was brought to us an account of the loss of function of the shoulder and slight pain.

Examination: Swelling and slight ecchymosis about the right shoulder. The right upper extremity was held limply at the side. Marked tenderness over the upper part of the humerus. Limitation of all movements of the joint, especially abduction.

Diagnosis: Fracture of the upper part of the humerus, confirmed by a subsequent Roentgen ray picture. (Fig. 5.)

Fractures of the shaft of the humerus: There were five such cases in our series. Two of these were in infants where the fractures occurred during delivery; one was in a child who had fallen from a wagon, striking upon his shoulder. In the former two the site of the fracture was near the center of the bone, just below the insertion of the deltoid muscle. The deformities were lateral displacement, the fragments lying parallel (Fig. 7). The lines of fractures of all three were practically transverse. In the two infants there was an accompanying wrist drop, probably due to some injury to the musculospiral nerve at the time of the fracture. This wrist drop gradually disappeared during the first two weeks.

The older child who had fallen from the wagon sustained transverse fracture, without displacement of the fragments. His history follows:

Case VI.—Sam M., eight years of age. One day previous to his visit to our clinic, he fell from a wagon and hurt his left shoulder. He suffered very little pain thereafter. He was brought to us on account of the loss of function of his left shoulder.

Examination: The left upper extremity was held limply by the side, there was swelling of the left shoulder. Crepitus, false mobility, deformity and ecchymosis were absent. All the movements of the shoulder were limited. A line of maximum tenderness was traced running transversely across the upper part of the humerus.

Diagnosis: A diagnosis of fracture of the humerus was made, and a subsequent Roentgen ray picture (Fig. 6) confirmed our diagnosis.

Treatment: Where there was a deformity (as in

Fig. 7.—Fracture of the humerus.

Fig. 7) it was reduced. Then strips of adhesive plaster were passed about the chest fixing the injured arm to the side of the body. The forearm was flexed upon the arm, the hand brought towards the opposite shoulder, the axilla protected by means of boric acid lint, and the fractured humerus pressed firmly against

the lateral chest wall by means of the encircling bands of adhesive plaster.

This method prevents the usual external angular deformities, and has the great advantage both of simplicity and security. This dressing is retained for about a week, when it is removed and replaced by a

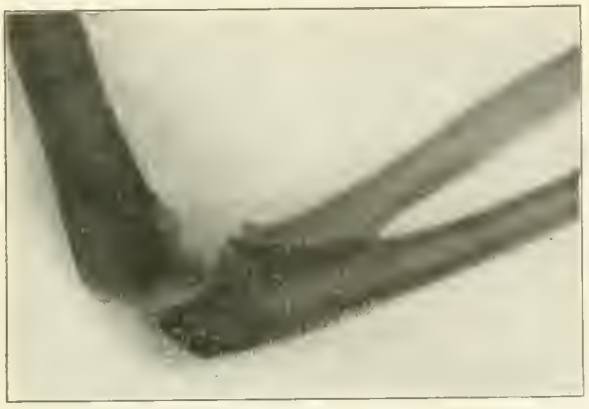

Fig. 8.—Case VII. Fracture of the external condyle of the left humerus.

new one. After another week it is dispensed with entirely. After-treatment was not necessary in these cases, but it is a good plan to give massage and movements to the shoulder before discharging the patients.

(*c*) Lower end of the humerus and in the elbow joint. There were forty-three cases of these fractures, divided as follows: Supracondyloid fractures, 10; internal condyles, 20; external condyles, 10; olecranon process of the ulna, 3.

The supracondyloid fractures were commonly caused by a fall upon the hand, the elbow usually being extended. The fractures were generally oblique, occasionally transverse. Very often there is a displacement backward and upward of the lower fragment. The condyles and the olecranon process were generally fractured by direct violence, as a fall, striking upon the elbow. The torn piece of bone in many cases remains intact, being held there by the periosteum; in other cases it is torn away and displaced (Fig. 9). The fragment may be dislocated in any direction.

The diagnosis in these elbow fractures is very difficult at first on account of the marked swelling and severe pain which are generally present at that time. Motion in the joint is painful and limited, occasionally abnormal mobility and crepitus may be present.

There were three cases of fracture of the olecranon process, all transverse, with slight displacement of the fragments. All responded to the treatment which will subsequently be described.

Case VII.—Anthony D., six years of age, fell and struck on his left elbow. Complained of pain and disability.

Examination: The left elbow was held in flexion at an angle of about one hundred degrees. Deformity, ecchymosis, crepitus and limitation of all movements were present. Tenderness was excruciating and localized to the external condyle of the left humerus.

Diagnosis: Fracture of the external condyle of the left humerus. A subsequent Roentgen ray picture confirmed our diagnosis. (Fig. 8.)

Case VIII.—Sidney E., eight years of age, fell on the outstretched palm of his left hand. This was followed by pain and disability.

Examination: The forearm was held in flexion of about one hundred and twenty degrees. There were swelling and ecchymosis about the left elbow. Deformity, crepitus, and false mobility were present. Tenderness over the lower part of the left humerus was excruciating. All movements of elbow were limited.

Diagnosis: A supracondyloid fracture of the left humerus, with upward and backward displacement of the lower fragment. A subsequent Roentgen ray picture confirmed our diagnosis. (Fig. 10.)

Case IX.—Alfred M., five years of age, fell and struck upon his right elbow. He complained of pain and disability.

Examination: The elbow was held in extension of about one hundred and forty degrees. There were swelling, ecchymosis and tenderness in the region of the olecranon process. Slight crepitus and false mobility were present.

Diagnosis: Fracture of the olecranon process, with a slight upward and backward displacement. Our diagnosis was confirmed by a subsequent Roentgen ray picture.

Treatment: The supracondyloid and condylar fractures were treated by the acute flexion position.

After the fracture has been reduced, the arm is fully flexed, so that the hand on the affected side rests upon the opposite shoulder and the elbow is carried well forward on the chest. In the majority of cases this position keeps the fragments in position. The forearm is now bandaged to the arm by figure-of-eight turns. Before applying the bandage the arm should be dried and powdered and a piece of boric acid lint placed in the elbow crease and axilla to absorb the perspiration and keep the parts dry. The wrist is kept in position by a sling about the neck. It is very desirable to take a Roentgen ray picture after a few days to see if the fragments are in good position. Should the Roentgen ray show a bad position the dressing should be removed and the deformity corrected.

At the end of a week or ten days the bandage is removed and passive movements are begun. In performing passive movements grasp the elbow with one hand and flex, extend, pronate, and supinate the forearm to its full extent. This should be done once only and repeated three times a week. Massage should be given once or twice daily. Grad-

Fig. 9.—Case VII. Fracture of the external condyle of the left humerus; forearm extended. Note the displacement of the fragment.

ually diminish the acuteness of flexion and at the same time lengthen the sling. Flexion must be maintained for at least three weeks. When the limb can be used, exercise should be added. These are described fully by the writer in a previous paper,

"Fractures of the Elbow," MEDICAL RECORD, January 15, 1916.

Treatment of fractures of the olecranon process.—These cases were treated by mechanical means and responded without resort to operation. The

FIG. 10.—Case VIII. Supracondyloid fracture of the left humerus. Note the posterior and upward displacement of the lower fragment.

method used, a very simple one, is one in which a straight plaster of paris splint is placed along the front of the arm and forearm, with a pad in the elbow bend so that the limb is not fully extended. The fragments of the olecranon are kept in position by means of narrow strips of adhesive plaster applied with their center above the fragment and the ends are brought obliquely downward to the sides of the splint below the elbow. The strapping requires daily inspection and frequent renewal. The marked effusion which was present necessitated the use of an ice bag.

Subsequent treatment should be begun as early as possible. The limb is retained in the extended position for three weeks. From time to time the splint is removed and passive movements are given. Care must be taken to avoid separation of the fragments. In spite of this early passive movement there was considerable stiffness, which was eventually overcome by persistent, careful massage, baking, active and passive movements, and exercises. It is very important in giving passive movements to remember that one can aggravate a synovitis of the elbow stretching the limb too vigorously, and in that way produce fresh adhesions and more limitation of function. A good way to prevent this is to stretch the limb within the painful limits, that is to flex the forearm up to the point where the patient complains of pain, and to extend it up to the point where the patient begins to complain of pain repeating within these limits.

Fractures of the Forearm.—There were 92 of these cases, of which 40 were fractures of the lower end of the radius, 20 were fractures of the shaft of the radius, 5 were fractures of the shaft of the ulna, 3 of the olecranon, and 24 were fractures of both bones.

Fractures of the lower end of the radius. The usual cause was a fall upon the outstretched palm of the hand, the elbow being somewhat flexed. Occasionally direct violence was the cause. The site of the fracture was generally about three-quarters to an inch above the articular surface. There were very few that showed any impaction and the deformity in these cases was very slight. Those that were impacted showed the characteristic deformity of Colles' fracture, *i.e.*, the silver forked deformity. Case X illustrates the average type of fracture present in these cases. The history of the case follows:

CASE X.—(Fig. 12.) Daniel P., seven and a half years of age. One day before coming to our clinic the patient tripped and fell on the outstretched palm of his right hand.

Examination: There was marked swelling and ecchymosis on the anterior surface of the lower part of the right forearm. Crepitus, false mobility and excruciating tenderness were present about three quarters of an inch above the articular surface. The movements of the wrist were all limited.

Treatment: If the fracture is an impacted one, complete reduction is essential before any treatment can be satisfactory. Subsequent adhesions and stiffness of the wrist must be guarded against. The adhesions and stiffness result from a tenosynovitis of the tendon sheaths in the neighborhood of the fracture.

Reduction: When possible reduction should be accomplished under an anesthetic. Extension and forcing the lower fragment forward is all that is necessary. Where no anesthetic can be given, reduction is effected by grasping the hand on the affected side, flexing and adducting it until the impaction is undone. Care must be taken to see that the displacement is rectified completely. After the fracture has been reduced, the fragments can be retained in their proper position by grasping the lower end of the bone between the thumb and fingers; the thumb is placed on the back of the wrist and presses the lower fragment forward, while the fingers press the lower end of the upper fragment backward.

Splint: A circular plaster of paris bandage extending from the elbow to the metacarpo phalangeal

FIG. 11.—Case IX. Fracture of the olecranon process of the right elbow. Note the slight backward displacement of the fragment.

joints, that is to the knuckles behind and the transverse crease of the palms in front, is now applied. The fingers should be left unconfined and the patient encouraged to move them, so as to prevent adhesions of the tendons to their tendon sheaths.

The forearm should be supported in a sling. A Roentgen ray picture should be taken as soon as possible after the bandages have been applied, so as to ascertain as to whether any displacement has occurred. If any has occurred the bandages should

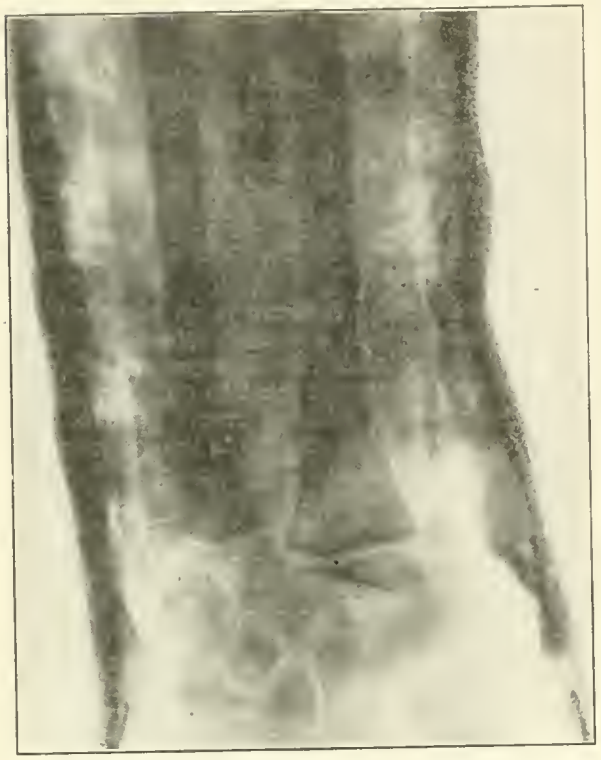

Fig. 12.—Case X. Fracture of the right radius.

be removed, the deformity corrected and the bandages reapplied.

Subsequent treatment: Where the Roentgen ray shows no displacement the bandages should not be removed until the end of ten days. At this time the bandages are cut laterally, so that there are two parts—an anterior and a posterior—which subsequently can be used as anterior and posterior splints. Passive movements of the wrist, combined with pronation and supination, are now begun. Care must be taken to avoid displacement of the fragments. For one week passive movements and massage should be given every other day. After this week has elapsed the anterior splint is dispensed with and massage, passive and active movements of the wrist and fingers given daily. At the end of the third week the posterior splint is dispensed with and the forearm supported in a sling for a few days, when this is discontinued and gradual use of the limb is permitted. Where marked edema and pain remained, baking and persistent massage usually overcame them.

The entire treatment averaged three weeks and the majority of the patients were discharged with no stiffness in the fingers or wrist. There was no atrophy of the thenar muscles, which atrophy we have found in a number of cases sent to us for treatment to overcome the weakness and stiffness of the wrist and fingers. To facilitate early return to the normal, we recommend that the limb be immersed first in hot water for ten minutes, then in cold water for three minutes, followed by massage, using olive oil while massaging. This is to be given twice daily.

Shaft of the ulna. There were five cases. Most of them were at the middle of the shaft and were caused by direct violence.

Shaft of the radius. There were twenty cases of this type, most occurring at the middle of the shaft, the result of direct violence (see Fig. 17).

Fractures of both bones of the forearm. There were a few of these cases that presented a fracture of the shaft of both bones, the site generally being about the center of the shafts. The vast majority were lower down, about an inch above the articular surfaces of the wrist. The former were generally the result of direct trauma, while the latter variety was a result of a fall upon the outstretched palm of the hand. Figs. 13, 14, 15, and 16 illustrate the fractures of both bones, low down, and middle of shafts, respectively. The report of one of these cases follows:

Case XI.—Milton F., six years of age. One day before coming to our clinic he fell, striking upon the outstretched palm of his left hand.

Examination: Swelling, ecchymosis, deformity and crepitus at the lower part of the left forearm. Distinct tenderness over the lower part of the radius and ulna about three quarters of an inch above the articular surface. There was absolute loss of function in the wrist joint.

Diagnosis: Fracture of both bones of the forearm, confirmed by a subsequent Roentgen ray picture (Figs. 13 and 14).

Treatment: As the treatment of fractures of the shaft of the ulna, radius, and both bones are the same it will be discussed under one heading. After reduction of the deformity, if one is present, apply a plaster of paris bandage extending from the middle of the arm above to the metacarpophalangeal joints below, leaving the fingers unconfined. The elbow should be held at right angles and the forearm midway between pronation and supination. The patient should be encouraged to exercise the fingers actively from the very first.

Subsequent traeatment: This dressing is retained for ten days, at the end of which time it is divided laterally, so as to form anterior and posterior splints. These are removed and passive movements and massage to the fingers, wrist, and

Fig. 13.—Case XI. Fracture of both bones of the forearm low down. Anteroposterior view.

elbow begun, care being taken to avoid displacement of the fragments. This massage and passive movements are to be repeated every other day for one week. After that every day, for about a week, active movements and exercises being gradually

added. The splints are gradually discarded and the patient permitted to assume his normal duties.

A few words about the management of fracture of the shaft of both bones. There are two important points to remember in the treatment of these fractures.

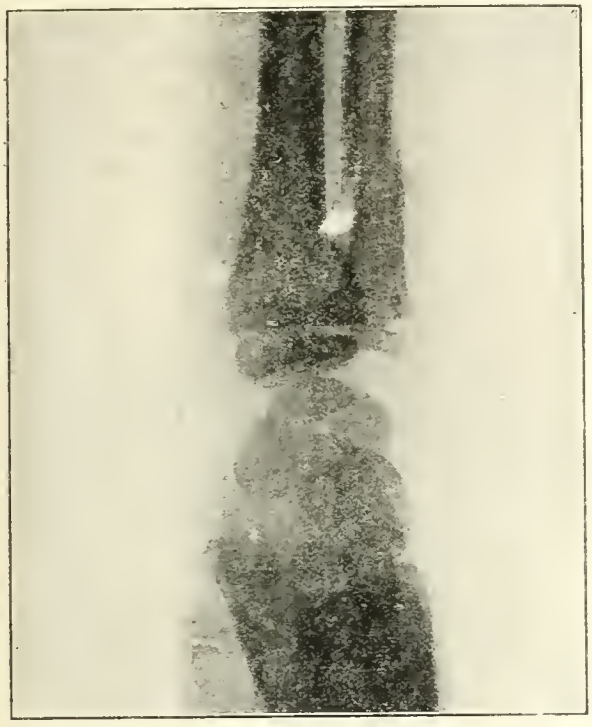

Fig. 14.—Case XI. Lateral view. Note the lateral displacement of the fragments.

1. Ununited fractures of the radius are fairly common, undoubtedly on account of improper fixation of the elbow, movements of pronation and supination being insufficiently guarded against.

Fig. 15.—Case XII. Fracture of both bones of the forearm. Lateral view. Note the deformity.

2. There is a tendency for the four fractured surfaces to be drawn toward one another and union may take place between them with complete loss of pronation and supination. This can be avoided by fixing the forearm so that pronation and supination are impossible. Fusion of fractured ends can be avoided by preventing all lateral pressure on the bones after proper coaptation. To be successful one must obtain proper reduction and proper immobilization. A pad between the shafts of the two bones is unnecessary as it could not separate the bone ends without exerting injurious pressure on the circulation.

The treatment of fracture of both bones low down, as far as the dressing and subsequent treatment are concerned, is the same as that for fracture of the lower end of the radius alone. They have been described fully under fracture of the radius.

Fractures of the Leg.—Shaft of the tibia. There were five such cases in our series. All were of the intraperiosteal variety, being the result of direct violence. Before coming to our clinic they were treated as contusions. The cardinal signs of fracture, namely, deformity, crepitus, and false mobility, were not present. Ecchymosis was slight and

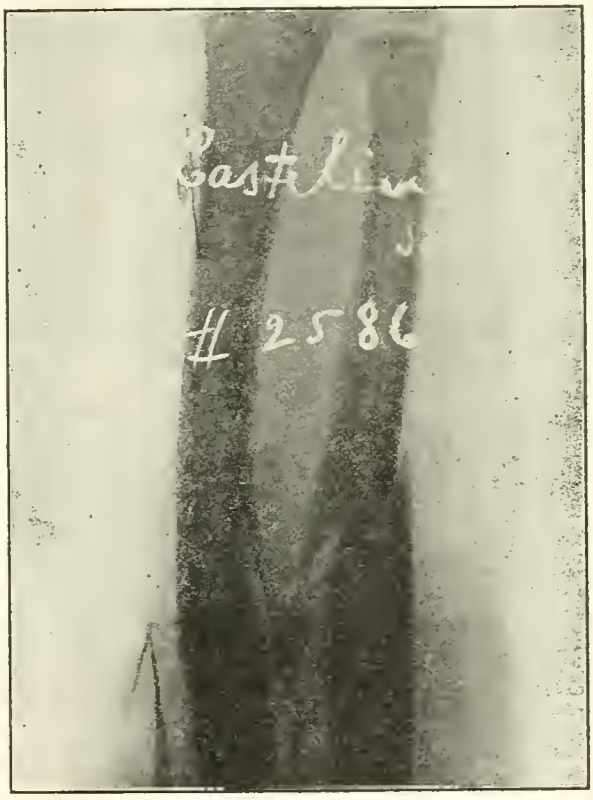

Fig. 16.—Case XII. Anteroposterior view.

appeared late, hence it was of little value in making an early diagnosis. The diagnosis was made by tracing a line of maximum tenderness. There was no loss of function in any of these cases, all having walked to the clinic with very little difficulty, the only complaint being of a slight pain when bearing the body weight on the injured limb and there was also a slight limp.

Treatment: The treatment consists of the application of circular plaster of paris bandages, extending from the base of the toes to just below the knees. After ten days the bandages are removed and passive movements of the ankle begun. The limb is then replaced in the bandages, which are removed daily thereafter for massage and passive movements. After four days the bandages are discontinued and active movements are instituted. These active movements are continued until the normal function of the limb is restored, which is usually within a week.

Fracture of the fibula. There were five cases in our series. One was of the linear type. The others showed a fracture of the lower end of the fibula; in some cases with a displacement backward of the foot. The fibula was fractured from an inch to an

Fig. 17.—Case XIII. Fracture of the shaft of the radius. Anteroposterior view.

inch and a half above the base of the malleolus, complicated in some of the cases, with a tearing away of the internal lateral ligament and the malleolus (Pott's Fracture).

Treatment: It is very important to obtain a very accurate reduction, followed by proper retention. Where possible, an anesthetic should be used. After proper reduction the limb should be fixed with the foot firmly inverted. This is best accomplished by means of a circular plaster of paris bandage extending from the ball of the toes to a point just below the knee.

We begin massage and passive movements early, and in that way we obviate the possibility of stiffness of the ankle. Owing to the readiness with which displacement recurs, the greatest care must be taken to fix the fragments while the joint is moved.

After about two weeks the plaster of paris bandages are cut laterally so that they can be used as anterior and posterior splints. Massage and passive movements are then begun. The limb is then replaced in the splints, which are removed daily so that massage and passive movements can be given. After one week of this treatment active movements are gradually added. The massage, passive and active movements should be given for three weeks before the patient is permitted to bear the body weight on the injured limb. If the body weight is borne too soon, the strain may produce a persistent condition of valgus.

It is a good plan after the patient is permitted to walk, to prescribe shoes with an eighth to a quarter of an inch lift on the inner side of the sole and heel. This shoe is similar to the one which we prescribe for weak feet and has proven of value in the subsequent treatment of Pott's fractures. These shoes are made for us by Mr. Max Deutsch of this city.

Where through faulty treatment a persistent valgus results and where the valgus is not overcome by the shoe alone, it may be necessary to supplement the shoe with strapping and later with a Whitman brace.

The patient should not be discharged until all movements in the ankle joint are free and painless. This is usually about six weeks after the onset of the injury.

Summary and Conclusions.—1. In treating fractures in children and infants one must always bear in mind the tender skin of the infant, its round agile body, and the movable cover of fat which envelopes the soft bones.

2. The tendency to heal is much more intense in children than in adults, the time of union is much

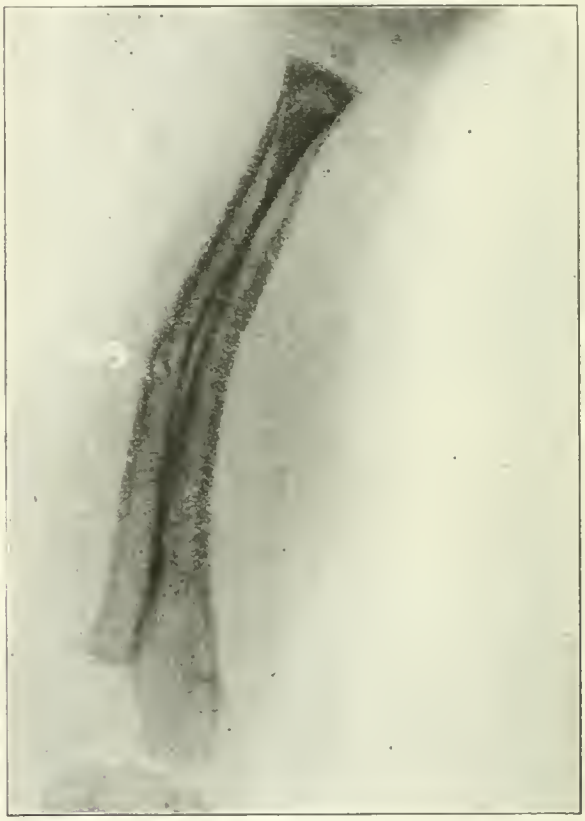

Fig. 18.—Case XIII. Lateral view. Note the deformity.

shorter, and immobilization should be of shorter duration.

3. A certain percentage of fractures in children do exist with the cardinal signs of fracture lacking, the diagnosis being made in these cases by tracing the point or line of pencil or maximum bone tenderness.

4. Where following an injury children refuse for any length of time to use a limb, especially if their attention is distracted from the injury, or when they are at play, bear in mind the possibility of a fracture.

5. One must always bear in mind the necessity of proper retention, as it is just as important as proper reduction in securing favorable results.

6. Early massage, passive and active movements are very important adjuncts in securing satisfactory results.

7. I wish to express my indebtedness to Dr. Samuel Kleinberg for his kind suggestions, and Dr. Jacob Bower for the Roentgen ray pictures.

1051 Boston Road.

WOMAN'S DUTY IN THE ANTITUBERCULOSIS CRUSADE.*

By S. ADOLPHUS KNOPF, M.D.,

NEW YORK.

PROFESSOR OF MEDICINE, DEPARTMENT OF PHTHISIOTHERAPY, AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; SENIOR VISITING PHYSICIAN TO THE RIVERSIDE HOSPITAL-SANATORIUM FOR THE CONSUMPTIVE POOR OF THE HEALTH DEPARTMENT OF THE CITY OF NEW YORK.

It is not an easy task to say in fifteen minutes what can be done in the antituberculosis crusade by the woman, poor or rich, married or single, young in years and experience, or rich in experience but young in heart, because her sympathies go out to her suffering sisters and brethren. I have, therefore, written down what I have to say so as not to overstep the time limit and so as to express at least the essential part of what I have in mind on this subject.

Every American woman should know that her sex does not disbar her from exercising the best qualities as a worker for the common good. Although she is not as yet privileged in all our States to have a direct voice in making the laws, she is required to obey. Her duty in the combat of tuberculosis, the disease of the masses, is primarily to acquire knowledge; secondarily, to use this knowledge for the prevention of the disease, and, thirdly, to render whatever personal service she can for both prevention and cure. She should know that in spite of all our efforts we are still losing annually well-nigh 200,000 people from tuberculosis in the United States; that of these nearly 50,000 are tuberculous children, and these children, figuring their average length of life at 7½ years and their cost to the community as only $200 per annum, represent a loss of $75,000,000. Such children have died without having been able to give any return to their parents and the community. Besides all this, many a tuberculous mother has had her life shortened because she bore one of these children.

The annual economic loss caused by the death of 150,000 adults, most of whom have died between the ages of 15 and 45, when their earning capacity should have been greatest, in addition to their maintenance during their years of illness, amounts to about $900,000,000 annually. Every woman should know that in spite of the great prevalence of the disease, and this fearful death rate, tuberculosis has been declared again and again by the highest medical authorities to be preventable and curable.

Women can help in the prevention of the disease by bearing in mind that although it is very rarely directly inherited, the tuberculous parent nearly always transmits to his or her offspring a weakness, a physiological poverty, which predisposes the children not only to tuberculosis but also to other diseases, particularly those of infancy and childhood. When in addition to its inherited weakness the child is exposed to close contact with the tuberculous father or mother, postnatal infection is sure to follow. For a tuberculous person in the active stage of the disease to kiss a child or to expose it to the spray ejected during a coughing spell (droplet infection); to have the child use the same spoon or cup used by a tuberculous individual before these utensils have been thoroughly cleaned; to expose the child to the inhalation of tubercle bacilli laden air, that is to say, to the inhalation of tuberculous dust coming from the dried and pulverized matter coughed up by the consumptive; or to feed the child milk from tuberculous cows, are some of the many ways by which the child born free from disease may surely become tuberculous.

What can women do to overcome these sources of infection? One thing is not to marry when actively tuberculous or in danger of becoming so, and not to marry a tuberculous man. If tuberculosis develops in either parent after marriage they should seek the advice of a competent physician, for if birth control ever has a *raison d'être*, it seems to me that it is when the parents are actively tuberculous, and particularly the mother; for in such instances prophylaxis not only means the prevention of a child coming to this world destined to invalidism, but it also means the saving of the life of the mother who so often succumbs as the result of the strain of the child-bearing period when she is herself afflicted with tuberculosis.

If there are already children in the family, they can be protected by scrupulous care and may remain healthy and strong. This care must consist not only in avoiding the above-mentioned source of infection, but by developing the child into a physically strong being which can resist the invasion of the tubercle bacillus. The mother should make an open-air baby of each of her children, feed them carefully and plentifully, keep their skin scrupulously clean, following the warm bath for the babies with a rapid rubbing with her hands dipped in cold water. The open-air kindergarten and the open-air school are the only proper places to educate a child predisposed or exposed to tuberculosis. Teach such a child breathing exercises; do not bundle it up, but dress it comfortably according to the season. At the time the girl grows into womanhood do not compress the organs in the chest and abdomen by tight lacing. It goes without saying that the mother, in no matter what station of life she may move, should also dress sensibly, and never again wear the trailing skirt which collected from the sidewalk tuberculous sputum and dirt containing the germs of diphtheria, pneumonia, and consumption, to be later on deposited on the carpets of the children's playroom.

A child born with a tuberculous predisposition should always sleep, if not in the open, at least in a window-tent or in a bed moved near the open window. Mother and teacher must watch such a child, and for that matter all children, to see that they do not overdo in physical and mental exercises. Our boards of education—and you women should always be represented on such boards—should see to it that the mental training of our children is not carried on to an extent to impair their healthy, vigorous physical development. To my mind in many schools there are too many useless studies, too much cramming, too much homework, and not enough play, outdoor life, and outdoor instruction. Let singing, recitation, geology, botany, and physical training alike for boys and girls, weather permitting, be carried out always in the open, and last but not least let the open-air school become the rule and the indoor school be the exception—at least for the lower grades. You would be surprised how much less tuberculosis, and other infectious and communicable diseases of childhood, we would have among children and how much better they would be prepared for civic and, if necessary, for military duty, and how much higher type

*Read by invitation before the General Federation of Women's Clubs, at their Biennial Conference in New York City, May 30, 1916.

of American men and women this change in our old-fashioned curriculum in the public schools would bring about.

Besides individual and family hygiene, outdoor life, and physical training, we must also have hygienic factories, workshops, stores, and offices, and must prevent overwork and malnutrition. It is obvious that these reforms must be obtained through legislation. But, alas! woman is as yet not a legislator. Nevertheless, you women of influence and power can do a great deal even before you are legislators. Make your influence felt so that dark bedrooms, congestion, overcrowding in cities and country, unsanitary workshops and sweatshop shall be done away with. Oppose with all your might that curse of child life known as child labor, which is still permitted in many States, be it said to the disgrace of our nation. Do not patronize industrial concerns when you know that their policy is to underpay and grind down your unfortunate sisters and brethren.

Our great Surgeon-General W. C. Gorgas was recently asked what he regarded the most important health sermon he could think of. I know that I cannot honor my illustrious friend, teacher, and superior officer better than by quoting before this distinguished assembly of American women his exact answer to this question: "I believe that all health officers should turn their attention to those measures which would tend to increase the wages of the poorest class of laborers. I favor that, as one of the basic cures of existing health evils, because it will have the effect of producing more thoroughly good sanitation than any more direct measures they adopt. How can the laborer earning $500 a year learn the benefits of good sanitation? He and his family must sleep in one little squalid room; the wife must cook and wash and the family must eat in the other room. It does not matter how much you would teach the process of sanitation, nor how much learning they receive on the subject of preserving health and preventing disease, it wouldn't do any good, because he hasn't the facilities to carry them out. But give him a better wage, so that he can add another room and remove the congestion and the breathing of the whole family in one sleeping room, and then you go to the very foundation of the health problem."

There is little for me to add to this message except to say that it should have been addressed not only to the health officers but to all physicians; not only to them but to all the men and women of the nation. Let me say in passing, and I believe I do not violate any confidence by making the statement, that our dear Major General Gorgas is a single taxer and I, too, consider myself an humble disciple of "Saint" Henry George. Higher wages, better feeding, and better housing will do away with much disease and misery. I venture to say that it will even help to combat alcoholism, for let it be remembered that the overcrowded, underfed, and badly housed laborer often seeks comfort and consolation in the cup so that he may forget his misery. But even as things are now, a great deal can be done by those of you who really wish to help in the prevention of both the direct and indirect causes of tuberculosis. The underfed school children should be able to purchase a substantial luncheon which can be furnished for very little cost; paying even ever so little for it will prevent pauperization.

Besides seeing that the underfed children receive at least one good meal while attending school we should provide also more playgrounds, small parks, and breathing places for them. Where land is expensive, as, for example, in our great City of New York, there are the thousands of acres of roofs that could be transformed into playgrounds and breathing places for children and tired-out mothers. Multiply public baths and see to it that swimming is made a part of the curriculum of every school and catastrophes like the Slocum disaster of twelve years ago will be accompanied by less loss of lives. See to it that more comfort stations are installed in our great cities.

Now, as a last word, what can you do toward the cure of the disease? Bear in mind that although I have said tuberculosis is curable, it is not curable in all stages. It is when the disease is recognized in the early stages that the tuberculous patient has the best possible chance of recovery. Let every mother remember the early symptoms: a long-continued cough, loss of flesh, a little fever in the afternoon, a little chill in the morning, frequent hoarseness, easy tiring, great susceptibility to catching colds, increased irritability, little streaks of blood in the sputum. These symptoms are often indicative of an approaching pulmonary tuberculosis. When in addition to some of these symptoms, even if no cough is present, you notice swelling of the glands or joints, lameness or difficulty in walking, running of ears, frequent nasal catarrhs, flabby skin, a general anemic appearance and pain on pressure over enlarged joint, the child is probably suffering from a local tuberculosis. Early discovery and timely and judicious treatment may prevent the child from becoming a cripple for life.

Any one, father, mother, relative, or friend, noticing the just mentioned symptoms in any individual, should endeavor to bring about a careful examination which may be the saving of a valuable life.

What else can the woman of power, wealth, and influence do in any community toward the cure of a tuberculous patient? Aid the community, in which there are not sufficient tuberculosis dispensaries, special hospitals, preventoria, and sanatoria for tuberculous adults and children, to establish these institutions and see that they are well equipped, well managed, and the patients well taken care of. There should be no uncared-for tuberculous patient in any civilized community. The untrained and uncared-for tuberculous individual, whether he lives in a palace or in a tenement house, in a first-class hotel or a lodging house, will constitute a center of infection. There are not nearly enough institutions for the care of the tuberculous in the majority of our cities and towns. Melbourne in Australia has given us the example by the community taking care of all tuberculous patients who cannot be or are not properly taken care of at home, and by enforcing all reasonable, humane, and sanitary precautions to prevent the further spread of tuberculosis. This disease, heretofore considered the most prevalent and most fatal, the City of Melbourne has succeeded in eradicating. Of course, Australia is a country where woman does not reign supreme, but where she is the equal of man. She labors and works for the good of the community side by side with man. I hail the day when her position in this country will be the same. But in the meantime she can do much by promoting all movements which tend to better the condition of the child and her less fortunate sister, the woman

of the laboring class, and thus help both directly and indirectly in the combat of tuberculosis.

I have only been able to give you some hints as to how you can help. But I am aware that you are all familiar with the opportunity for service which is offered in almost every field of human endeavor to the woman who truly wishes to be helpful. One of our greatest philanthropists, a man who has given away millions for the betterment of his kind, the venerable Andrew Carnegie's favorite saying is, "Service to man is the highest service to God." To modify this for the occasion, I would wish to say that the service which the modern woman, that is to say, the woman of highest ideals, imbued with the greatest desire for service to her fellows, is destined to render to mankind, is nothing less than the salvation of the human race. Woman once in the council of city and State, there will be less social injustice, disease, and pestilence; woman once in the council of nations, there will be, it is hoped, no more desolation and no more war.

THE REQUIREMENTS OF THE GONOCOCCUS FOR ITS NATURAL AND ARTIFICIAL GROWTH.

By LEVERETT DALE BRISTOL, B.S., M.D.,

UNIVERSITY, N. D.

PROFESSOR OF BACTERIOLOGY, UNIVERSITY OF NORTH DAKOTA; DIRECTOR OF THE STATE PUBLIC HEALTH LABORATORIES.

The successful growth of the gonococcus on artificial culture media is one of the most uncertain procedures with which the average bacteriologist has to deal. A few men, after careful study of the subject, have had uniform results in obtaining scanty growth on special media. Carrying out the directions of these men, others have had little or no success. From this it would seem that some variation must exist in the different food ingredients as well as in the environmental influences recommended as necessary for the artificial growth of the organism; and that up to the present time we have found no medium which may be used by all investigators with satisfactory results. Because of the present demand for complement fixation tests and vaccines, as well as a necessity for further study of the organism itself, a uniformly successful growth of the gonococcus is absolutely essential.

This paper is based upon preliminary work which has been done in an endeavor to answer the following questions:

A. Why should the gonococcus grow so rapidly and abundantly in the human urethra, and on other mucous membranes of the body, and not at all in the test tube on ordinary media, and only fairly well on special media?

B. What is the essential constituent of the human body which is necessary for the growth of the gonococcus?

C. How can we best take advantage of this necessary material in artificial media?

The subject is divided; the first part dealing with the requirements of the gonococcus for its natural growth, while the second part has to do with the requirements of this organism for its artificial development outside the body.

No extended discussion is necessary as to the requirements for the natural growth of this diplococcus. It is common knowledge that the mucous membranes of man or woman are the sites of predilection for the development of the gonococcus. The mucous membranes of the male and female genitals and their adnexa are the ones usually involved, although in rare instances gonococcus infection has been noted on the membranes of the mouth, nose, ear, conjunctiva and rectum. The infection is common, also, as a secondary process in joints and tendons. The organism in the human body, as is demonstrated by its prodigious growth, finds what it needs in regard to moisture, uniform temperature, proper chemical reaction, and specific food substances. As regards the environmental conditions of light, temperature, reaction and moisture, the gonococcus should find what it needs in the lower animals, with the possible exception that the normal temperature of some animals may run from one to three degress (centigrade) higher than that of man. Growth of the gonococcus and typical gonorrhoea have practically never been found in the genitals of lower animals, as a result of natural infection or artificial inoculation. It hardly seems reasonable that the slightly higher temperature in these animals is sufficient to always inhibit the growth of the gonococcus. It is evident that the important thing which the gonococcus needs for its growth and multiplication is probably a specific food substance, and that this is present in the human body but absent from or in a different form in the body of lower animals. The only other explanation is that there exists in the lower animals some substance, or substances, of a metabolic nature which antagonize and inhibit the gonococcus in its growth, and that these substances do not exist in the human body.

Of the principal food substances which occur in the human body upon which bacteria may thrive, there is none more important than protein material. We know that a certain amount of protein is necessary in artificial media for the growth of most microorganisms. Bacteria seem to differ as to the kind of protein required. Most organisms are not concerned over the special quality of protein needed and will grow with simple proteins from various sources as food. A few bacteria seem to require something more than simple protein. It appears that the chief food substance which the gonococcus requires is protein in nature, that this protein is more complex than simple protein, and that it has special qualities characteristic of man and not of lower animals. (The study of precipitation reactions has demonstrated that there are definite biochemical variations between even the same proteins of man and of lower animals.)

According to recent classification, proteins may be divided into three groups: (1) Simple proteins; (2) conjugated proteins; (3) derived proteins. Members of the first group are always found in the body as constituents of muscles and blood serum, and tissues in general. Conjugated proteins are more complex and consist of a combination of protein and a non-protein substance. Combinations of protein with a carbohydrate or its derivatives are known as glucoproteins, or glycoproteins. Nucleoproteins are combinations of protein and nucleic acid. The other conjugated protein of importance is hemoglobin, a combination of globin and hemochromogen, the latter being an iron-containing substance. The third group, or derived proteins, we will not here consider.

It will be noted that the conjugated proteins are characteristic of certain localities and tissues of the body, while the simple proteins are much more general in their distribution throughout the body

tissues and cells. It has been found also that there are specific differences between the conjugated proteins of man and lower animals, as well as between the simple proteins of man and animals.

Let us fix our attention on the exact localities where the gonococci grow in the human body. The mucous membrane is the best soil, and membranes upon which the larger mucous glands open is the best field, while small areas surrounding the openings of these glands, or even inside the glands, are the spots where these gonococci grow the most luxuriantly and persist for the longest time.

Gonococcus infection may be classified under two heads: (1) Primary; (2) secondary. Primary infection is almost always confined to the mucous membranes which open to the external surface of the body, such as the urethra in the male, the vulva, urethra, vagina in the female, and the conjunctiva, rectum, mouth, nose, and ear in both sexes. As a rule infection takes place by direct contact of the diseased mucous membrane, and its infectious secretions, with an uninfected mucous membrane. Secondary infection is spread by either (*a*) direct continuity of mucous surfaces and direct extension to other tissues and organs (a more or less localized process), or (*b*) a general systemic infection. It should be mentioned that the usual sites of primary infection may be involved in a secondary way. Cowperitis, prostatitis, epididymitis, in the male; Bartholinitis, metritis, salpingitis, ovaritis, peritonitis, in the female; periurethral abscess, cystitis, and nephritis, in both sexes, are illustrations of the first group of secondary infections, while septicemia, pyemia, endocarditis, and arthritis are examples of systemic infection.

What specific substance in the body, common to all these localities, serves the gonococcus for its growth? It has been stated above that this substance is probably protein in character. What protein is characteristic of epithelial mucous membrane and glands (as well as of their secretion, mucous) and is present in variable amounts in connective tissue (as found in tendons), and in cartilage (as found in joints), as well as in blood and synovial fluid? Although other proteins are present, it seems to the writer after a careful study of the subject that human glycoproteins, especially the human mucins and related compounds, are the specific substances which the gonococcus requires for its growth in the body. As mentioned above, the glycoproteins belong to the class of conjugated proteins and have a protein group and a non-protein group, the latter being a carbohydrate or a derivative of a carbohydrate. This carbohydrate compound was the first to be isolated from an animal tissue and is called "glucosamin." It is a nitrogen-containing derivative of dextrose. Of these glycoproteins, the mucins and mucoids are the most important for our consideration.

The mucins and mucoids are acid in character, contain no phosphorus, have a low carbon and nitrogen content, a high percentage of oxygen due to the carbohydrate group, and an increased amount of sulphur. The amount of carbohydrate may vary to a great extent. Unlike most of the other proteins the mucins and mucoids are not coagulated by heat. They may be precipitated by acetic acid and are only slightly soluble in an excess of acid. True mucins are derived from epithelium, while mucoids are derived from connective tissue. "True mucins are found," as Mann says, "in most of the slimy fluids of the body. They are excreted by the goblet cells on the surface of mucous membranes and by the larger mucous glands which are found in different parts of the body." Besides its presence in the secretions of the above-mentioned cells and glands, mucin is found in bile and a so-called "pseudomucin" is found in ovarian cyst contents. This pseudomucin differs from true mucin in not being precipitated by acetic acid. Of the connective tissue mucins, or so-called "mucoids," the ones which most resemble true mucin, are the mucoid in tendons, the "osseomucoid" in bones, the "chondromucoid" in cartilage, and the mucoids of the cornea, vitreous humor, and umbilical cord. Embryonic and young connective tissues in general have rather high percentages of mucoid substances. The white of egg contains a considerable amount of a glycoprotein called "ovimucoid." A mucoid is also found in human blood serum and urine. Investigators have found variable amounts of mucoid in ascitic, hydrocele, and synovial fluids, and have given to it the name "serosamucin."

Is it not of considerable significance that where mucins and mucoids are present in greatest amount there we find the gonococcus thriving the best? Is it not because of the mucin or mucoid present that the gonoccoccus grows readily on mucous membranes (especially in the genital tract where additional large mucous glands are found), as well as on the conjunctiva, cornea, and vagina in infants (where cells are greater in number and connective tissue is still more or less mucoid in character), and in tendons, cartilage, and synovial fluid?

Now that the *theoretical* requirements of the gonococcus for its natural growth in the human body have been considered, let us proceed to a brief discussion of the *practical* requirements for its growth in artificial media.

It is a fact that the gonococcus will not multiply in our ordinary culture media which contain simple animal proteins, and that our best artificial culture media for this diplococcus are largely composed of those human fluids, such as ascitic, cystic, or hydrocele fluids, blood-serum, or urine, in which these human mucoid substances, of the conjugated protein group, are found to a greater or lesser extent. Another suggestive fact is that by adding glucose to any medium its value as a soil for the growth of the gonococcus is considerably enhanced. We have already stated that a carbohydrate, glucosamin, is characteristic of mucins. Even egg-white, which contains considerable ovimucoid, has been used by investigators with some success in growing this micrococcus.

Like other bacteria, the gonococcus requires a certain amount of moisture for its proper development. Its resistance to drying, as well as to light, variations in tempeature, and other external conditions, is rather less than that of most bacteria. Authorities differ as to the extremes of temperature which the gonococcus may stand. The temperature of the body is probably the best for its growth. The upper extreme is generally given as anywhere from 38° C. to 42° C., while the lower extreme varies from 25° C. to 30° C., according to different workers. Most bacteria require a neutral or slightly alkaline reaction in artificial media. A few seem to grow best in an acid medium. Varied advice concerning the best reaction for the gonococcus is met with, although the consensus of opinion seems to indicate that a slightly acid reaction to phenolphthalein, or a neutral or faintly alkaline reaction to litmus is the most desirable.

To determine further the value of human mucins and mucoids as specific food substances for the gonococcus, the writer has been carrying on preliminary experiments, using human umbilical cords as the source of human mucin for artificial media. So far as the work has gone, the results are encouraging, though not complete enough for publication at this time.

ESOPHAGEAL STRICTURE.

By HENRY FRENCH GOODWIN, M.D.,
AND
CHESTER HENRY KEOGH, M.D.,
CHICAGO, ILL.

A CASE of impassable stricture (esophageal), reported in the *Journal A. M. A.* April 15, 1916, preceded by the caption "of interest because of the age . . . and the medical things devised in the case, which may be of help to others," leads us to report the following case.

The case we present is not unknown to the staffs of Wesley Memorial Hospital, of the Children's Memorial Hospital, of the Charity Hospital, and of the Chicago Postgraduate Hospital, where the patient received treatment. The case, after recovery, was presented before the South Side Branch of the Chicago Medical Society some years ago. The patient is alive and in good health. In stature he is not below the average for his age.

Lawrence R., then aged three years, drank lye some time during the summer of 1909. He was attended by Dr. H. F. Goodwin during the month of January following and thereafter. Dr. A. B. Kanavel was then brought into the case. He performed a gastrostomy. Through the ventral opening the patient was fed liquid food through a tube for many months, as the esophagus had become impassable to all food solid or liquid. Even colors in solution failed to appear in the stomach by way of the stenosed esophagus. Men skilled in the use of the esophagoscope were not successful in their efforts to penetrate the stricture. Dr. Goodwin then invited Dr. Keogh to join him in the case as his colleague, and together they went to work to try and save the little patient.

The child was given an anesthetic. Failing with other methods, a Fenger flexible sound was passed by one of us through the adventitious opening in the stomach, through the cardiac opening and up through the stricture to the fauces. A silk thread was tied to the tip of the sound and drawn down and out through the opening in the stomach. This thread was kept in situ, until a better substitute was found—one which a child could not sever by biting—a piece of soft flexible rubber-covered braided tinned copper wire, in caliber about the size of wrapping twine. The Abbe saw was not used. Knots and small spheres were drawn through the stricture from below upward. Later, cylinders, modified with hemispherical ends, were used. There was some difficulty in slowly dilating the stricture by this retrograde method. There was also considerable difficulty in passing the dilator through, from above downward by this traction, even after the stricture was fairly well dilated, and upon the whalebone or flexible shaft commonly used all of the so-called olive tips which were tried, from above, failed to pass the stricture. It is to explain the form of tip then used by us, with success, that this article is written. These tips were home-made, of brass, plated. The mechanics of the idea will appeal to the good sense of anyone.

It had been shown by radiograph that a small diverticulum above the stricture possibly impeded the progress of the olive-shaped tips of general usage. So one of us made a tip in the form of a simple cylinder. Upon a flexible shaft, from above, this made a triumphal journey through the stricture to the stomach and back again. After that the conduct of the case was quite simple. The gastrostomy opening was allowed to heal by granulation. From time to time, for several months, the stricture was dilated. During the treatment we used oxychloride of bismuth and olive oil. At no time was the treatment severe enough to cause the child discomfort. He learned to swallow the cylinder fastened to a flexible shaft—a Fenger flexible exploring sound was made to fit the purpose—the cylinder passed on down to the stricture. Then a piece of piano wire was slipped into the lumen of the sound and the cylinder was gently forced through the stricture.

A pointed olive tip seeks the posterior wall of the esophagus and probably engages the cul-de-sac of a diverticulum; while a cylinder, of proper size, will pass through a stricture complicated by a small diverticulum, for the reason that a cylinder throughout its length has a bearing surface upon the posterior wall of the esophagus and tends to maintain its axis parallel to that of the esophagus.

The literature is replete with cases of esophageal stricture. Perhaps the reports of Guisez in the French literature are as complete as one would wish to find, though the complete record of such cases is not without value. Guisez had reported, at the time this case was presented before the medical society, thirty-five cases. Of these, twenty-eight strictures were the result of caustics. The ages of his patients varied from twenty-one months to sixty-four years.

"Electrolysis Circulaire" was his favorite method of treatment, which, as far as we know, is not extensively practised in this country. Twenty-eight of his reported cases were complete recoveries.

6021 WOODLAWN AVENUE.
4316 DREXEL BOULEVARD.

REPORT OF A CASE OF ADIPOSIS DOLOROSA.

By CHARLES M. NICE, M.D.,
BIRMINGHAM, ALA.
PHYSICIAN TO THE BIRMINGHAM INFIRMARY.

THE following case seems worthy of a brief report.

S. T., a country girl, single, aged twenty-two, accustomed to general housework.

She had always been robust, but at the age of sixteen gradually took on an increase in weight. At this time she began to have pain in the abdomen similar to that she now complains of. She was taken to a hospital and operated upon for gallstones and appendicitis. She had the usual diseases of childhood. She is the oldest of six children, all of whom are living. There was a vague rheumatic and tubercular history on the paternal side and a nervous history on the maternal side. Specific history could not be ascertained.

She had been confined to her bed for six months previous to her admission in January, 1916, to my service in the infirmary. She refused to try to sit up or work. Her mental condition did not allow any expressions other than pain, which she complained of day and night, and at all times referring to her left abdomen. Her sleep was of short duration only and she moaned almost constantly. She refused to eat except in very modest amounts of liquids. She would not talk.

On examination she showed a ruddy complexion and an extreme degree of adiposity. This fat was evenly distributed over the body, but hanging in huge folds on either side of the abdomen, thighs, and arms. Her weight was 262 pounds, height 5 feet, 3 inches. Her head was constantly turned to the right side. The eyes showd a marked exophthalmus with Stellwag's sign. The teeth were covered with sordes and her tongue was badly coated and breath foul. No enlargement was made out of the thyroid, neither could there be of any other glands.

Her abdomen showed a large scar from the appendical region nearly to the costal margin. Nothing could be felt through the enormous fat layers which were as tumefactions on each side of the abdomen. On the left side she complained of pain on the lightest palpation. Another obvious change in her appearance was due to the adiposity of her hands and feet, greatly enlarging their size and giving them a fan-shape appear-

ance and especially enlarging and flattening their distal ends.

The heart and lungs were negative. Vaginal examinations showed no abnormality of the sexual organs. The reflexes in the lower extremities were depressed. She appeared to have full motor power, but refused to use it, even in an effort to move herself in bed, lying always in the same position. Some soreness was complained of when pressure was made over the deep nerves. Her blood-pressure was normal. The urinary excretion was not increased and examination of it was negative.

The temperature was 98.5° in the mornings; 99.6° in the afternoons. The pulse varied from 80 to 96 and was regular. Hemoglobin was 75 per cent., white blood cells, 6,000; polymorphonuclear, 73 per cent.; small lymphocytes 18 per cent., large 9 per cent.; eosinophiles, 2 per cent.; malaria negative. Skiagraphs of her head did not reveal anything that could be interpreted as a tumor or abnormality. Wassermann and luetin reactions were negative.

When the diagnosis of adiposis dolorosa had been made she was given increasing doses of thyroid extract, but without effect. Opiates at times were resorted to. She was fed only by forcing.

After a time she was given daily doses of pituitary extract hypodermically. Improvement began by the end of the first week. The mental apathy was seen gradually to disappear, the exophthalmus became less and less severe, her pain was moderated, the tongue cleared, and she began to eat with a fair appetite.

No other medication except necessary purgatives were given and in two weeks she began to walk. At the expiration of the seventh week she left my care, at which time she complained of no pain.

Suggestions were given her home physician to continue the treatment and later advices received from him inform us that she has gradually decreased in size, works as a normal girl, and her mental condition has greatly improved.

This case is reported because of the possibility that she may have been operated upon six years previously for the same conditions which she has recently had, namely; adiposis dolorosa with the customary painful fatty tumors (Dercum's) and that there were no gallstones or appendicitis as supposed.

Again there was a close relationship between the thyroid and pituitary gland as evidenced by the physical findings.

Finally, the administration of pituitary extract gave almost immediate and continuous improvement until the present, but the future outcome, of course, is questionable.

Woodward Building.

Medicolegal Notes.

Insufficient Evidence of Malpractice in Treating Fractured Arm.—In an action for malpractice, it appeared that on January 25, 1911, the ulna of the plaintiff's right arm was broken by the kick of a horse. After receiving emrgency treatment he placed himself in the defendant's care. The negligence claimed was that owing to the defendant's lack of care and skill, the fractured bone failed to unite, and also that he failed to discover that the radius was dislocated at that time or later during the treatment. On January 26, after an examination of the fractured arm with a fluoroscope, the defendant set the arm, using splints to retain the broken bone in place. On the following day he discovered that it would be necessary to wire the fractured ends of the bone and had the plaintiff go to a hospital, where the operation of wiring was performed by the defendant. After the operation, the defendant dressed, bandaged, and otherwise treated the arm until March 29, when the plaintiff consulted another doctor, Dr. Rowley. The plaintiff's evidence was to the effect that Dr. Rowley found a dislocation of the radius; that there had been no union of the fractured bones; that the wire used in securing it had broken, and that pus had developed in the wound, all of which conditions, except the formation of pus in the wound, were indicated by an X-ray photograph of the plaintiff's arm taken on that date. At this time the plaintiff placed himself in the care of Dr. Rowley, who treated the injured arm until about May 1, when he and Dr. Lewis operated by cutting off the head of the radius, declared necessary in order to reduce the dislocation, and reset and wired the fractured bone, which, however, as under the defendant's treatment, from some cause unknown to Drs. Rowley and Lewis and contrary to their expectations, failed to unite. This evidence merely showed what the defendant did professionally, but there was no evidence that there had been a want of ordinary care on the defendant's part. Not only so, but the evidence of both Dr. Rowley and Dr. Lewis, who were the only witnesses called for the plaintiff competent to testify whether the defendant had exercised reasonable care and skill, was to the effect that the nature of the fracture was such as to demand the wiring of the bone, and that the wire used was such as surgeons generally used in such cases; that in operating upon the fracture they used like wire, which likewise broke in the adjusting.

No evidence was offered showing that, if the dislocation of the elbow existed at the time the defendant undertook the treatment of the fractured arm, the defendant was negligent in failing to discover it. So far as appeared, he was called upon to set the fractured bone. No intimation was given him of injury to the elbow. Whether or not he should, under the circumstances, in the exercise of ordinary and reasonable care and skill, have discovered such condition, assuming it to have existed, was a question for expert testimony, and none was offered. Conceding that Dr. Rowley, as stated by him, had no difficulty on March 29 in discovering the dislocation, nevertheless this fact did not show a want of ordinary care and skill on the part of the defendant in failing to discover it, since Dr. Rowley, by reason of superior learning and advantages, may have been a man possessing far more than ordinary skill in his profession.

It was held by the court that the evidence wholly failed to show any lack of care and skill on the part of the defendant in setting and treating the fractured bone of the plaintiff's arm, and also failed to show when the dislocation occurred, or that a physician in the exercise of ordinary care and skill, in treating the plaintiff, should under the circumstances shown, have discovered the dislocation and treated it.—Houghton v. Dickson (Cal.) 155 Pac. 128.

Chiropractors Must Be Licensed.—A chiropractor held himself out as being able by adjusting the bodies of his patients to enable them to throw off disease, but sedulously refrained from calling his operations treatments, and notified his patients that he was not a doctor or physician. Texas Penal Code, 1911, Article 750, declares that it shall be unlawful for anyone to practise medicine in any of its branches upon human beings who has not registered in the district clerk's office of the county in which the resides his license for so practising, while Article 753 declares that any person shall be regarded as practising medicine who shall publicly profess to be a physician or surgeon, or shall treat or offer to treat, any disease or disorder, mental or physical, by any system or method, or to effect cures thereof, and charges, directly or indirectly, money or other compensation. The Texas Court of Criminal Appeals held that the accused, who collected fees for his adjustments, not having procured the required license, was guilty of practising medicine without a license.—Teem v. State (Tex.) 183 S. W. 1144.

Evidence in Malpractice Cases.—The plaintiff in an action against a surgeon for negligence in unsuccessfully grafting skin to an empty eye socket for the purpose of permitting the use of an artificial eye, has the burden of proving that the operation was negligently and unskillfully performed. A verdict for the defendant was held to be sustained by evidence that twenty-four years before a similar operation had proved unsuccessful, as did also two other operations which had been performed after that of the defendant.—Nye vs. Clark, 193 Ill. App. 505.

Liability of Charitable Hospitals. — In Pennsylvania the law is well settled that a charitable hospital for the care and treatment of the diseased and injured and its trustees charged with the management thereof are not liable for the negligence of a nurse in administering poison to a patient by mistake, the nurse not being incompetent, nor the corporation or its officers negligent in selecting her. This doctrine seems to be in harmony with the decisions in the federal courts.—Paterlini v. Memorial Hospital Assn. of Monongahela City, 229 Fed. 838.

ACUTE ANTERIOR POLIOMYELITIS.

THE present rather serious epidemic of acute anterior poliomyelitis in this city again calls attention to our ignorance regarding the nature and mode of spread of this scourge of childhood. The disease, although its causative agency is not known, behaves very much like an acute infectious disease, and, indeed, it is almost universally accepted that it is of germ origin. Inoculation experiments carried out by many workers, by Flexner and Lewis of the Rockefeller Institute and others, have been successful in passing the disease to animals, but not in finding the organism. It probably belongs to a class of organisms, as yet unidentified, that pass through the ordinary filter media.

At one time it was believed by many that this disease is a fly-borne one, and that the large biting stable-fly is the offending insect. It would seem that in large cities the stable would be a negligible factor, but in the congested centers it can play quite a part as a general nuisance and a menace to health. It is more probable, however, that the ordinary house fly is the culprit, yet against this is the fact that the prevalence of the disease is not wholly confined to fly time. Suspicion has also, and with some reason, been directed 'against the flea. A more plausible theory than that of the biting fly, and one that does not exclude the agency at times of the house fly, is that the disease is spread in the same way as influenza or common colds, for it is known that the pathogenic agent is contained in the nasal secretions of the sick.

The high morbidity and the disastrous effects of poliomyelitis certainly demand that every precaution against its spread be taken, and therefore among other things the regulations covering the management of stables should be made very stringent. In view, however, of the more probable means of infection, it is very proper to consider and to treat the disease with respect to quarantine and isolation in the same way as the other acute infections of childhood, and this holds even though instances of apparently direct contagion are rare. The assemblage of children in epidemic localities has been discouraged or forbidden, and although this with the closing of moving picture shows to children doubtless seems cruel to them, in face of the danger now threatening nothing that has been done to conserve the public safety can be accounted too harsh. The amount of infection or even the exact foci of infection are difficult to determine because many of the cases are believed to be abortive without paralytic symptoms, or so slight as to escape detection. On the other hand, there is little doubt that many cases of ordinary convulsions in children are diagnosed, in times of epidemic, as infantile paralysis in the so-called preparalytic stage, and so the prevalence of the disease is made to appear greater than it really is.

The amount of paralysis that will remain permanently after an attack of acute poliomyelitis is hard to estimate. There is usually a great deal of repair, but it is often spread over a long period, even as long as two years. Even in apparently paralyzed muscles, if they retain their faradic irritability to but a slight degree, there is hope of recovery under proper treatment. A great deal of harm is often done by commencing irritative treatment, such as massage and electrical stimulation, too early, that is during the acute stage of the disease. Later this treatment must be carried out relentlessly. Even when the paralysis is permanent the physician can now hold out a good deal of hope if there are nearby muscles that are intact. Transplantation of tendons, so that the healthy muscles can do the work of the paralyzed ones, is an advance in surgery that has come to stay and will help to mitigate the evil of infantile paralysis.

THE PARATHYROIDS.

ABOUT one year ago (May, 1915) Eugene H. Pool contributed, as the "Collective Review" in the *International Abstract of Surgery*, a summary of what was then known regarding the anatomy and physiolog of the parathyroids, their relation to tetany, and the therapeutic measures, experimental and otherwise, which had been employed in tetany parathyreopriva. In view of the disappointing results following medical treatment and homotransplantation in tetany parathyreopriva, Pool strongly emphasized the necessity of giving these structures as wide a berth as possible when operating upon the thyroid. A second publication on this subject appeared in the *Annals of Surgery* for January, 1916, in a paper by Pool and H. C. Falk entitled "The Surgical Anatomy of the Thyroid with Special Reference to the Parathyroid Glands."

In the earlier years of operation for goiter, when the function of the thyroid was very imperfectly understood and that of the parathyroids not even suspected, removal of both lateral lobes of the thyroid at the same sitting was not infrequently practised, and this was sometimes followed by the gradual development of myxedema, occasionally by acute or chronic tetany. Cachexia strumipriva and tetany were for a long time regarded as different phases of but one condition—a condition which was supposed to be dependent upon insufficiency of the thyroid function. Although the normal gross anatomy and histology of the parathyroids were accurately described by Sandstroem in 1880, their physiological significance was not appreciated until Gley, in 1891, demonstrated their relation to tetany. While, normally, there are four parathyroids, occurring in pairs, it has long been known that this

number and arrangement are inconstant. Careful examinations at autopsy have sometimes shown a smaller number, but for reasons which will appear later it is certain that when less than two have been discovered some have been overlooked or the individual has had aberrant parathyroids. Recognition of the parathyroid glandules, none too easy at autopsy, is still more difficult under the conditions that obtain at operation; and there are many operators of large experience in this class of surgery who do not hesitate to say that they have never been able positively to identify parathyroids as such while operating.

Under these circumstances, therefore, it is essential that the manifold relations of these bodies to the lateral lobes of the thyroid be thoroughly understood by the operator. In recent years, since the relation of the parathyroids to the development of tetany has been definitely shown, operators have generally endeavored to avoid them; or, if malignant involvement of the thyroid or other conditions have made it necessary to disregard the danger of removing the parathyroids in relation to one lobe, special pains have been taken to preserve those on the opposite side when operation upon the other lateral lobe was necessary. Then the only parathyroids the individual possesses may be in relation with the lobe that is being operated upon; since it is usually difficult, if not actually impossible, to identify these structures in the course of operation, their safety can be secured only by leaving a slice of the posterior portion of the thyroid substance. In case of the removal of the parathyroids in relation with the thyroid lobes tetany will result unless the individual is so fortunate as to possess aberrant parathyroids. If but one parathyroid is left the development of tetany is probable; for Iversen's analysis of the cases of human tetany apparently showed that at least two parathyroids are, as a rule, essential.

Why is it that so many cases of tetania parathyreopriva have been reported in spite of the fact that practically all surgeons are well aware of this danger? The studies of Pool and Falk throw considerable light upon this question. Under what has been considered normal conditions the parathyroids are sufficiently removed from the thyroid substance so that when a lateral lobe of the thyroid is enucleated in accordance with the usual method (splitting the surgical capsule anteriorly and shelling out the lobe within this, meanwhile keeping strictly to the line of cleavage of the true capsule during this process) the parathyroids remain attached to the surgical capsule or are even posterior to this, in which latter case they should not come within the field of operation at all. So far as Pool and Falk's series of autopsy sections was concerned this happy state of affairs existed in less than 50 per cent. of the cases. In their studies the tissues of the neck anterior to the spine were removed at autopsy in twenty-five cases. The tissues were cut transversely in thin layers and a search was made for the parathyroid glands. As illustrating the difficulty in identifying these bodies it should be stated that these were not cases of goiter, hence the number and relations of the parathyroids may be considered representative; yet in spite of extreme care but 60 parathyroids were found out of a theoretical 100.

But it was the situation of those found with reference to the surgical capsule that is of especial interest to the surgeon. The sixty parathyroids found were grouped as regards their relation with the thyroid and its surgical capsule as follows: Twenty-six, or 43.3 per cent., lay external to the surgical capsule at sufficient distance from the thyroid to be safeguarded in an intracapsular extirpation of the lobe. Nine, or 15 per cent., were so situated in relation to the capsule as to make it doubtful whether they would be saved in an intracapsular removal of the lobe. Twenty-five, or 41.7 per cent., were in such a position that they would almost certainly have been removed with the thyroid in an intracapsular extirpation. In the case of unilateral intracapsular removal of the left lobe, this examination showed that two parathyroids would have been sacrificed twice and two would probably have been sacrificed twice; in the case of the right lobe two parathyroids would have been sacrificed twice and two would probably have been sacrificed once. Thus the operation of unilateral intracapsular lobectomy is attended with a risk that two parathyroids will be removed in 8 per cent., or in 14 per cent. if the doubtful cases are included. They also found that in intracapsular removal of both lobes four parathyroids would have been sacrificed in 4 per cent. of the cases; four would very probably have been sacrificed in 8 per cent., and four would have been at least endangered in 12 per cent.

Among the authors' conclusions are that the relation of the parathyroids to the thyroid and its capsule is not of necessity the same for the whole set of parathyroids in an individual. Also that since usually two parathyroids lie on each side, and inasmuch as two parathyroids apparently can satisfy the demands of the body, the chance that tetany will develop as the result of extirpation of one lobe is extremely remote. It is reasonably safe, therefore, so far as tetany is concerned, to perform complete intracapsular extirpation of one lobe. It is, however, emphasized that for the prevention of tetany the posterior part of the lateral lobe must always be left on at least one side; and even when only one lobe is operated upon safety is better assured by leaving *in situ* the posterior part of that lobe.

STILL ROOM FOR IMPROVEMENT IN THE TRAINING OF NURSES.

In the dark ages of medicine the chief instruction students received was what they were able to absorb from daily contact from a physician whom they accompanied on his rounds. Later lectures and clinics were added where the students were brought into touch with the practice of medicine as illustrated by varying personalities. That was yesterday; to-day he hears lectures for four years, the latter two of which he also attends clinics and then frequently takes a year or two in a hospital. To-morrow he will have a five years' course, the last of which will be almost wholly clinical, and following this he will be

obliged to spend at least one year in a reputable general hospital before he is allowed to practice his profession.

With this increase of efficiency in the training of physicians will come, we hope, more enlightened methods of fitting nurses for their profession. The theory at present seems to be analogous to that held by the parents who advocate throwing babies into the water where they must either swim or drown. The probationer steps from school or counter, or whatever sphere has engaged her activity, into the hospital, dons her uniform and rubber heels, the patients are there, ill, requiring nursing, and she must nurse them forthwith, and often the experienced nurse who is supposed to be her preceptress hurries through a few perfunctory directions to her and hastens away to duties of her own. The bewildered probationer, left to her own devices, potters about and usually avoids making mistakes by doing nothing. A few days later she is left alone on the ward for a while, the resident physician enters, orders an alcohol sponge and is astonished when she tells him she has not the least idea how to give it. Or she is left in charge of a typhoid patient who complains of a severe pain in the abdomen but, fearful of disturbing the doctor unnecessarily, she makes no report of it.

The above is purposely put in a somewhat heightened manner. In many hospitals a sincere effort is made to give instructions in the elementals of nursing before trusting a pupil to her own resources and in many cases the probationer is of a type which assimilates the details almost instinctively and displays a knowledge amounting to intuition in emergencies.

It would seem that a course of lectures and demonstrations should be given to a prospective nurse before she is allowed to enter the wards, instead of some time after. The powers of the superintendent of nurses are usually much too arbitrary, moreover. It may happen that a probationer is dropped at the end of a few months at the pleasure of the head nurse who often acts largely on the reports of nurses in charge of wards, some of whom may not have been in training themselves longer than a year. With such a system it is easy to see how personal animus or lack of patience with a beginner may terminate abruptly a career which would otherwise be successful. We all know successful doctors who showed no great promise in their student days. Following such a course of lectures there should be a carefully graded series of instructions in the wards by experienced nurses and these should follow each other in such a logical sequence that there would be no danger of the nurse being left to execute duties which were beyond the stage of her training.

The nurse having been graduated, the next desirable step would be the universal adoption of laws which prevail in some States, that is, in regard to registration. No nurse should be allowed to practise until she has passed an examination by a State licensing board comprising both theoretical and practical nursing. After the system sketched above had been in operation for a few years we would find an R. N. as significant in its way as an M. D.

A PLEA FOR PURISM IN MEDICAL WRITINGS.

WITH his characteristic love for contention, Dr. Charles A. Mercier, the distinguished English psychiatrist, has again cast his hat into the ring. In a letter to the *British Medical Journal* for May 20, he assails vigorously the style of the average medical writer, who, he claims, shows an extreme paucity of vocabulary together with a lack of accuracy in the use of words. By way of illustration he quotes a recent article in which "marked" or "markedly" was used twelve times in ten lines. This is of course inexcusably tautological, but Dr. Mercier seems to wish to exclude this unfortunate adjective entirely, whereas it may be used quite properly to denote anything which is noticeable, conspicuous, or emphasized in any way. He also objects to a patient "developing" a disease and, strictly speaking, he is right, although medical custom seems to sanction the use of the word in this sense, but when he says that " 'to develop' is not, except in photography, a transitive verb," he is contradicted by Webster who gives seven applications of "to develop" as a transitive verb. Dr. Mercier couches his argument in his usual vigorous style, using such expressions as "shockingly overworked," "vile travesty of English," and "repulsive jargon."

As a matter of fact, while here and there we find instances of inaccuracies or inelegancies of style in medical writing we are practically never at a loss to decide what the writer meant to convey and that, after all, is the principal requirement of this kind of literature. It does not seem that a report on the result of a thousand typhoid vaccinations for example should be judged by the same criteria which we would apply to an essay in the *Atlantic Monthly*. A medical article is valuable if it adds something to our knowledge of disease and is not expected to be a well of pure English undefiled. Now and then we are fortunate enough to have writers who can combine medical worth with elegance of diction, as witness Oliver Wendell Holmes, S. Weir Mitchell, and G. Stanley Hall.

Whatever be the merits of the question raised by Dr. Mercier, who is probably not appreciated at his true value by his colleages in England, it is sure to set medical writers to self-examination and even surer to arouse a storm of protest. In fact the issue of the *British Medical Journal* for May 27, which has just come to hand, contains two letters, one taking exception to all the points made by Dr. Mercier, as well as indicting his taste in the matter, and the second one in the main commendatory, but accusing him of that unpardonable crime of misquotation.

THE CUP THAT CHEERS.

AMONG the incidental matters which are tossed about like uneasy corks upon the stormy waves of international affairs in Europe since the war began, the subject of alcohol is agitated now and then. Germany goes on her way serenely consuming her beer, Russia is vodkaless, France has restricted the heavier liquors, and England is betwixt and between. The "rum ration" still exists although many a wordy battle has been fought over it, but two blows have been dealt the home liquor traffic—the

abolition of treating and the limiting of the hours when liquor may be sold. Everyone reacts to alcohol according to his individual psychology even if we cannot all portray our reactions as vividly as Jack London does in "John Barleycorn." Certainly the optimistic way to look at it is as M. C. Fiessinger does. In a recent address before the Academy of Medicine in Paris he stated that wine activates the internal secretions, stimulates the association of ideas, and excites the affective states. He says that among the moderate wine drinkers mental originality is more constantly renewed and impulses of the heart and active goodness are more often in evidence. He believes that the happy genius of the French mind is due to their national beverage. Dr. Fiessinger's eulogy was taken exception to by some other members of the Academy, notably MM. Linossier and de Fleury, and probably would not be accepted unqualifiedly here. It is true that the effect normally produced at the time of the ingestion of alcohol is somewhat as he describes, but it seems to be rather a question of temporary paralysis of inhibitions and we are all too familiar with the pathology of alcoholism to endorse the effervescence of our French colleague.

Success of Pasteur Treatment of Rabies in the Lyons District.

In contrast with the defective results reported from certain Pasteur institutes throughout the world, the failures being set down to causes beyond control, not a patient treated in the Lyons Institute during 1913-14 was lost. The total number treated was 723. Of this number 122 received the intensive treatment. In 446 cases the animals were proved to have rabies, while in 277 the existence of the latter was only suspected. The report made by Dr. Rochaix in the *Journal de physiologie et de pathologie générale*, which was published only last April although bearing the date September 15, 1915, contains no comments and few control figures. A clean score has been the rule, and but 8 patients have died since the treatment was begun in 1900. In 1912 there were 2 deaths. The morbidity shows a distinct drop in June, while in August it seems at its minimum. It is highest in the short month of February, the antithesis of August. The biting animal was a cat in 32 cases and a cow in 1; in all other cases a dog.

Nyctalopia in Soldiers.

The European war has brought to light the existence of nyctalopia in the troops, most of which is doubtless acquired. It seems to be largely a transitory state due to fatigue or nervous depression. The condition is frequent, about 10 per cent. suffering. The highest incidence is in the winter months when the nights are longest. Some cases are congenital while others seem dependent on trench life. Anomalies of refraction frequently coexist. No doubt the physical fatigue, nervous tension, and moral disquiet play a causal rôle. The treatment consists in correcting anomalies of refraction, and the use of tinted glasses. The men also improve under rest and variety of diet. The above data are taken from an article by Weekers the Belgian ophthalmologist, in the *Archives d'ophthalmologie*, March-April, 1916. The author and others state that the condition is a new one in military medicine. Day vision suffers but night vision more so. Nyctalopia as we know it may occur without hemeralopia; but in most of the cases occurring in soldiers both conditions exist in the same subject. The night blindness is much the greater military disqualification because a soldier is unfit for patrolling or sentry work, and becomes fearful of a surprise.

News of the Week.

Base Hospitals Promised.—As announced last week, the New York Red Cross now has eight base hospitals ready for service whenever they may be called for and wherever they may be required to go. The Red Cross has also taken charge of the Border Hospital at Brownsville, Tex., and has appealed for funds to enlarge, equip, and maintain it. This hospital, which was established for the care of the American troops patrolling the border, treated 350 patients during 1915, many of them wounded Mexicans. It consists at present of only a few frame cottages without the necessary equipment.

The New York State Department of Health, through Dr. A. B. Wadsworth, director of the division of laboratories and research, has placed its facilities at the service of the State military authorities. If it is desired, the laboratory will ship to the surgeon of each regiment and other units in the field, boxes containing typhoid vaccine and serums for tetanus, diphtheria, and spinal meningitis. The department has also offered to send a bacteriologist to the State mobilization camp for the making of diagnoses in the field.

Deaths in New York City.—The Department of Health announces that for the week ending June 24 the death rate in New York City was 12.24, representing a total of 1,311 deaths, as compared with a rate of 12.22 for the corresponding week of last year, when the total number of deaths was 1,277. Twelve deaths due to infantile paralysis were reported, eleven of them occurring in the Borough of Brooklyn, in certain sections of which the disease is epidemic. The other contagious diseases showed a decreased mortality; and in the deaths due to pulmonary tuberculosis a very appreciable decrease occurred, though this was to some extent offset by the increase in the deaths reported from other tuberculous diseases. Owing to the inclement weather during the week there was an increase in the number of deaths due to bronchitis, and the mortality of the degenerative diseases also was increased. The death rate for the first twenty-six weeks of 1916 was 14.82, as compared with 15.10 for the first half of 1915.

Poliomyelitis Still on Increase.—Up to July 5 there had been reported to the Department of Health 623 cases of poliomyelitis, of which about 75 were in Manhattan, 3 in the Bronx, 5 in Queens, 8 in Richmond, and the remainder in Brooklyn. One hundred and thirty-four deaths have occurred since the first of the year, almost all of them during the last three weeks, giving a mortality of over 20 per cent., which is nearly four times as high as during the epidemic of 1907. Of the deaths, all except two were of children under ten years of age. The Commissioner of Health has enlisted the help of the police, street cleaning, and tenement house departments in fighting the epidemic, the police to check violations of the sanitary code in the infected districts, the street cleaners to pay special attention to the streets therein, and the tenement house in-

spectors to keep watch of the houses in which cases have been reported. Placards written in English, Italian, and Yiddish have been printed and posted in certain parts of the city, giving warning of the danger of infection. The Commissioner also has the aid of the staff of the Rockefeller Institute, Dr. Simon Flexner having addressed a meeting of Brooklyn physicians at the Polhemus Clinic on July 1, and both he and Dr. H. L. Amoss having conferred with the members of the Department of Health. As a result of a meeting held at the office of the Commissioner on June 30, the following orders were sent out:

"All patients must be removed to hospitals where the conditions of the home are not equal to those found in the most modern hospitals. These conditions must include absolute isolation, perfect cleanliness, a special nurse who must not come in contact with other members of the family, sunshine and fresh air.

"For those whose homes cannot afford these facilities special pavilions have been set aside in hospitals in each borough. In Brooklyn is the Kingston Avenue Hospital, where there are now forty patients; in Manhattan is the Willard Parker Hospital, foot of East Sixteenth Street. A pavilion has been set aside on North Brother Island for The Bronx and a pavilion of the magnificent new Queensboro Hospital at Jamaica for Queens."

The origin of the epidemic has not been determined, but as the first cases occurred among the Italians in the dock district of South Brooklyn, it is possible that the disease may have been imported from Italy. A special watch is being kept at Quarantine, but no cases have been discovered.

Open New Hospital.—The Queensboro Hospital, representing the result of years of effort on the part of the New York City Department of Health to provide adequate facilities for patients ill with contagious disease in the Borough of Queens, was opened on June 28, with Dr. Charles T. Sharp as resident physician. The hospital has accommodations for eighty patients, and has been built at a cost of $76,000. Several interesting features have been embodied in the construction. The ground floor of the south wing, for instance, contains twenty separate rooms, each opening both on a central corridor and on a porch running around the building. These rooms constitute "The Sieve," and in them will be kept for two weeks all patients entering the hospital, especially when there is any doubt as to the diagnosis or as to the existence of a complicating infection. For "The Sieve" there is a separate diet kitchen and nurses' room, and by an ingenious placing of windows all the patients are under the constant observation of the nurse. The ground floor of the north wing contains three wards with a capacity of twenty beds, to be devoted to diphtheria, scarlet fever, and measles, and the second floor of the building contains two wards in each wing, as well as a small operating room, nurses' room, etc. The third floor contains the dormitories for the nurses and employees. A notable feature of the wards is the introduction of glass partitions between the beds to prevent the reinfection of convalescent patients.

Dispensary Fellowships.—The Harvard Medical School has recently established four fellowships to be awarded to graduates in medicine and to be known as the Boston Dispensary Fellowships. The duties of the Fellows will be to give a portion of their time to clinical work in the district service of the dispensary, treating the sick in their homes, and a portion to such study, teaching, or laboratory, research or clinical work as may be assigned by the Medical School. The stipend of a Fellowship will be $500 when the physician gives part time, or $750 when he devotes his entire time to the work. Appointments will be made jointly by the authorities of the Medical School and of the Boston Dispensary, and the application should be made to the Dean of the Harvard Medical School, or to the Director of the Boston Dispensary, Boston. The Fellowships are open to the graduates of any medical school of good standing who have had a hospital training or its equivalent. Negotiations are now pending between the Boston Dispensary and the Tufts Medical School with a view of making similar arrangements for a Fellow for next year.

Medical School Prizes.—The Yale University School of Medicine announced on June 17 the award of prizes for the year as follows: The Ramsay Scholarship, established in memory of Dr. Otto G. Ramsay, and given to a member of the junior class of unquestioned ability and character, to Harlan B. Perrins of Seymour. The Parker Prize, left by Dr. Frank J. Parker, for the fourth year medical student who, in the judgment of the Faculty, has shown the best qualifications for a successful practitioner, to Lloyd L. Maurer of New Haven. The Perkins Scholarship for the first year student making the best record, to Clifton R. Scott of Bovina Center, N. Y. The Campbell gold medal, in memory of James Campbell, M.D., professor of diseases of women and children from 1866 to 1899, given for the highest rank in examinations during the course, to Joseph Russo of New Haven. The Keese Prize, in memory of Hobart Keese, M.D., for the best thesis at graduation, to Louis H. Nahum of Hartford.

Vacancies in Clinic.—There is an opportunity for two assistants in the department of diseases of digestion and metabolism at the German Polyclinic, Second Avenue and Eighth Street, New York. Physicians who have had some chemical training are preferred. The hours are from 2 to 4 P.M. on Tuesdays, Thursdays, and Saturdays. Application should be made to Dr. A. I. Ringer at the German Polyclinic.

Must Report Tuberculosis.—The Bureau of Tuberculosis of the North Carolina State Board of Health is calling the attention of the physicians in the State to the law requiring them to report all cases of tuberculosis under their charge to the Bureau within seven days after the recognition of the disease. It is estimated that at present only one-third of the cases of tuberculosis in the State are being reported, and since the Bureau can accomplish nothing without the co-operation of the physicians and the heads of institutions for the treatment of the disease, it is prepared to enforce the law, even by prosecution of the delinquents.

London Red Cross Fund.—A dispatch from London states that the Red Cross fund of the London *Times* has reached a total of $20,000,000, the largest amount ever raised in such a campaign by a newspaper.

Dies at 105.—Mrs. Mary Monroe of Binghamton, N. Y., died at her home on June 28, after a short illness, at the age of 105 years and 8 months.

Street Accidents.—The National Highways Protective Association reports that during the month of June, 44 persons were killed by vehicular traffic on the streets of New York, 35 by automobiles, 2 by

trolleys, and 7 by wagons. During the first six months of this year, 152 persons were killed by automobiles, as against 137 during the corresponding period of 1915, while throughout the State, excluding New York City, 100 persons were killed in the same way.

American Hospital Units.—A dispatch from Berlin tells of the departure from that city of two American surgical units which had recently arrived there. One unit, under the charge of Dr. Paul F. Martin of Indianapolis, Ind., has been sent to Budapest, and the other, under Dr. John R. McDill of Milwaukee, Wis., to Cologne. It is stated that the units had to obtain in Berlin all the necessary supplies with the exception of two dozen rubber gloves, because the British Government refused to permit the passage of their equipment through the blockade. The gloves alone were passed.

Pennsylvania Commencement.—At the 160th annual commencement of the University of Pennsylvania, held June 21, the degree of Doctor of Medicine was conferred on seventy-three graduates. Dr. Charles Karsner Mills, formerly professor, and now emeritus professor, of neurology, received the honorary degree of Doctor of Laws.

Dr. Fred H. Albee received the honorary degree of doctor of science from the University of Vermont, Burlington, at the 112th commencement of the university on June 28.

Dr. S. Lewis Ziegler of Philadelphia has been elected a member of the Board of Trustees of Bucknell University.

Dr. Zinke Honored.—Dr. E. Gustave Zinke of Cincinnati, who has recently resigned as professor of obstetrics in the University of Cincinnati College of Medicine, was the guest of honor at a dinner given by his colleagues in the university and among the profession in the city. Dr. Zinke was presented with a silver loving cup.

Broad Street Hospital.—Dr. A. J. Barker Savage has been appointed superintendent of the new Broad Street Hospital, New York, and the following physicians have been elected members of the Board of Directors: Dr. John F. Erdmann, Dr. L. A. McClelland, Dr. George Gray Ward, Jr., Dr. Ralph A. Stewart, Dr. Charles Gennerich, Dr. W. T. Helmuth, Dr. W. H. Crump, and Dr. W. H. Dieffenbach.

Gifts to Charities.—By the will of the late Mrs. Helen C. Juilliard of New York, St. John's Guild and St. Luke's Hospital of this city receive bequests of $100,000 each, and the New York Orthopedic Hospital and Dispensary a bequest of $50,000. In addition, St. John's Guild receives a contingent interest of one-half of a bequest of more than $100,000, the latter to be used for an addition to the hospital of the guild at New Dorp, Staten Island.

An additional gift of $165,000 to Mt. Sinai Hospital, New York, was recently announced by Mr. Isaac Guggenheim and his brothers, the gift supplementing their previous gifts of $500,000 for the erection of a private pavilion to be known as the Guggenheim Memorial. It will now be possible for the hospital to erect a pavilion having accommodations for 122 private patients, making it the largest building of the kind in the city.

By the will of the late Charles W. Kolb of Philadelphia, bequests are made of $100,000 each to the Samaritan Hospital and to Temple University.

Obituary Notes.—Dr. Everett P. Courtright of Newark, N. J., a graduate of Jefferson Medical College, Philadelphia, in 1890, formerly attending physician to St. Michael's Hospital and the Foster Home, Newark, and a member of the Medical Society of New Jersey and the Essex County Medical Society, died at his home on June 28, aged 49 years.

Dr. Rudolph Kindig of Philadelphia, a graduate of the Philadelphia College of Pharmacy and of the Jefferson Medical College, Philadelphia, in 1887, and for twenty-five years physician to the Swiss Benevolent Society, died at his home on June 17, aged 51 years.

Dr. Thomas Kirkpatrick of Garnett, Kan., a graduate of the University of Illinois, College of Medicine, Chicago, in 1883, died at his home on June 11, aged 58 years.

Dr. James Edward Leary of Lowell, Mass., a graduate of the College of Physicians and Surgeons, Baltimore, Md., in 1894, died suddenly at his home on June 11, aged 43 years.

Dr. Thomas Walter Long of Newton, N. C., a graduate of the New York University Medical College, New York, in 1885, and a member of the Medical Society of the State of North Carolina, died recently at his home, aged 58 years.

Dr. Joel H. Rieger of Kansas City, Mo., a graduate of Columbia University, College of Physicians and Surgeons, New York, in 1872, died at the German Hospital, Kansas City, on June 14, after a short illness, aged 66 years.

Dr. Joseph E. Caviness of Lillington, N. C., a graduate of Baltimore University School of Medicine in 1890, died at his home, after a long illness, on June 15, aged 70 years.

Dr. Grafton W. Gardner of Atlanta, Ga., a graduate of the Oglethorpe Medical College, Savannah, in 1861, died at his home on June 19, aged 86 years.

Dr. John T. Sweeny of Jeffersontown, Ky., a graduate of the Hospital College of Medicine, Louisville, in 1906, died at his home, after a long illness, on June 16, aged 36 years.

Mr. Joseph Ferris, pharmacologist at Bellevue Hospital for over twenty years, during which time he compounded nearly 500,000 prescriptions, died at the hospital on July 1 from cerebral hemorrhage.

Obituary.

JULIUS HAYDEN WOODWARD, M.D.

NEW YORK.

Dr. Julius Hayden Woodward of New York, professor of diseases of the eye at the New York Post-Graduate Medical School since 1908, and director of instruction in ophthalmology since 1913, died at his home on July 2, aged 58 years.

Dr. Woodward was born in Castleton, Vt., and was graduated from Cornell University in 1879 and from the College of Physicians and Surgeons, New York, in 1882, the same year receiving the degree of doctor of medicine also from the University of Vermont, College of Medicine. After practising for some time in Burlington, Vt., and serving as professor of laryngology, and later of ophthalmology in the University of Vermont, he removed to New York in 1897, where he had since lived. He was a member of the New York Academy of Medicine, the Medical Societies of the State and County of New York, the Vermont State Medical Society, the American Academy of Ophthalmology and Oto-Laryngology, the American College of Surgeons, and the Society of Alumni of Bellevue Hospital, and a life member of the Société française d'ophthalmologie.

Correspondence.

POLIOMYELITIS IN BROOKLYN.

To the Editor of the Medical Record:

Sir:—Perhaps at no time within the present generation has there arisen such a state of public alarm almost bordering on panic as in the case of the present epidemic of poliomyelitis in Brooklyn. The newspapers have published complete reports of the distribution of cases and of the fatalities, and these reports together with the placards posted and the leaflets distributed by the Board of Health have brought home to the population a keen sense of the gravity of the situation. The deep concern of all parents—indeed, of all people who are interested in the well-being of children—is intensified by the fact that the fatal or maiming blow of poliomyelitis does not fall merely upon weak or neglected children but strikes with almost equal force those who are apparently in perfect health and are properly cared for in sanitary homes.

Health Commissioner Emerson is to be commended for the prompt and energetic manner in which he has faced the present crisis. There can be no question that the removal to an isolation hospital of all cases that cannot be isolated at home, as now enforced by the Health Department, is a wise measure and the first important step necessary in combating the spread of this disease. At the date of writing there are about 200 cases of poliomyelitis in the Kingston Avenue Hospital of Brooklyn, and there is provision for 300 more. It is to be hoped that the spread of this disease will be checked long before the resources of the hospital are taxed to their limit, but unfortunately, if we are to be guided by past experience, the ravages of this disease will not be spent until early fall. Before another month New York will probably face the biggest problem which it has had to solve during the fifty years of existence of its Health Department, namely, the problem of providing adequate hospital accommodations for its cases of infantile paralysis.

This brings one to the subject of health preparedness, a timely one indeed, and one demanding of municipal, State, and national authorities as much attention as any other kind of preparedness. Here comes an unseen foe creeping with insidious step into hundreds of homes, killing and maiming the most helpless. The public stands aghast and a dozen or more health inspectors and a dozen or more nurses are added to the forces already mobilized to deal with preventable disease. The irony of the situation requires no comment. If one were to calculate the economic loss to the body politic occasioned by the ultimate incapacity of and the care for dependent cripples, he would find that the appropriation by the city for emergency purposes to meet the present situation of a sum of money far less than the cost of a single superdreadnaught would result in a substantial saving to the public treasury. Although money cannot buy public health any more than it can buy individual health there is an indispensable financial outlay of considerable magnitude required in the prosecution of all public health campaigns. Would it be too much to ask of the metropolis of the Western Hemisphere, indeed, of the richest city of the world, that it summon to its service at once the best sanitary talent that it can command?

Among the distinguishing characters of the present epidemic are the high degree of its virulence and the atypical character of many of the cases. The virulence is attested by the high mortality of 20 per cent. Within a period of two weeks the writer has seen four fatal cases. A striking illustration of the high degree of infectivity of the virus in the prevailing series of cases is afforded by the following experience: There have come under the writer's observation in the Children's Medical Service of Dr. Le Grand Kerr at the Methodist Episcopal Hospital two of the three children of a family, all of whom were infected with poliomyelitis about the same time. The first child, a six-year-old boy, was admitted to the hospital on the third day of his illness, in coma, with widespread paralysis of the limbs, trunk, and diaphragm. The case was one of typical Landry's paralysis. Death occurred within two hours. Two days later the sister of this child, two years of age, was admitted in the preparalytic stage of the disease. A widespread paralysis began on the second day following admission, involving all of the limbs and the muscles of the back of the neck. The mode of progression of the paralysis which began in the legs and then extended to the arms and neck made us apprehensive that we were dealing with another instance of the Landry type of paralysis. Fortunately, however, the disease did not extend to the respiratory muscles. The little patient has survived the dangerous period of her illness. It is impossible to state to what extent, if any, the early diagnosis in the preparalytic stage and the various protective and therapeutic measures instituted may have served to prevent a lethal outcome in this case. At any rate the results emphasize the importance of making an early diagnosis. About the time that this patient was admitted to the hospital, the third child in this family, a boy seven years old, was under the care of the family physician at home. The prominent symptoms of his illness were fever, hyperesthesia, and delirium. Examination of the cerebrospinal fluid showed that this was also a case of poliomyelitis. The patient made a complete recovery without paralysis. This was probably an instance of the abortive type of the disease. The above series of cases constitute an extremely rare, if not singular, instance in which poliomyelitis has affected three members of a family at the same time, and in which each case has represented a different type of the disease.

There may be more than mere accidental significance in the fact that, with possibly one exception, poliomyeltis has tended to prevail in New York City in epidemic type every two years since the great epidemic of 1907 with its 2,500 or more of reported cases. It may be noted, in passing, that the extensive Swedish epidemic so carefully studied by Wickman occurred in 1905. There have been outbreaks of this disease in New York City in 1909, 1911, and 1913, and according to this apparent law of periodicity a return of this disease was to be expected in 1915. Although a number of cases were reported in that year from various parts of the city they did not constitute an epidemic.

The writer had the opportunity of studying at close range seventeen out of a total of fifty-one cases of poliomyelitis reported in the Borough of Brooklyn from January 1 to December 1, 1911. During the same period there had been 171 cases reported in the Borough of Manhattan. The epidemic was far less extensive than that of 1907, and slightly less so than that of 1909. But the distribution of the Brooklyn cases and the circumstances attending them impart considerable inter-

est to them, particularly with reference to the light they throw upon our present experience with this disease. It was noted on comparing the different wards of the Borough in which the cases were reported that the number of cases in each ward was directly proportionate, not to the number of people in the ward, but to the density of the population. Another important fact brought out was the observation that the epidemic of 1911 practically spared the 26th ward, a thickly populated district in which the disease had prevailed extensively in 1909. This accorded with the observation that had been made in other epidemics in different parts of the world, namely, that communities that are visited by poliomyelitis in one epidemic are spared when the disease returns to a city in epidemic form. Poliomyelitis provides an instance of the epidemiological law of community resistance or immunity. According to this law, during an epidemic there are a large number of individuals who suffer from mild or latent types of the disease to which they are thereby rendered immune. In the present epidemic of poliomyelitis in Brooklyn the disease is prevalent in a section of the Borough in which only a few scattered cases occurred during the previous visitations.

4. Report of a Case of Sacroiliac Strain Following Symphyseotomy.

1. **Movements in Medicine.**—David L. Edsall in his address discusses the altered relation of the medical profession to the public at large. He says that as a result medicine has become a much more complex profession, and a new and very important character has been added to the calling. The doctor has always been somewhat cloistered from the world of affairs, and, as a consequence, he has often avoided, and even resented, anything that interfered with his freedom of action; and this, together with the fact that there were few positions of dignity open to medical men in which they were parts of a system, or were subordinate to higher authority, has made the general idea of being a part of a machine moving in necessary coordination with other parts usually distasteful. But the developments of recent decades have shown beyond a peradventure that the broadest and most beneficent activities of medical men in preventing and eradicating disease have in later times, and will continue to be, not individual researches or individual struggles with disease, but organized systems of attack, in which every one, whether in senior or junior positions, will be no longer a free lance but subordinate to the system, and dependent upon it for his success. The character of the medical profession is being everywhere more or less profoundly influenced in another way. For many years it was customary to adopt an attitude almost solely of defense in dealing with disease. In recent times the attitude has become aggressive, and there has been a massive and organized attack upon the immediate causes of disease that are most accessible. As a part of this movement we are now considering compulsory sickness, invalidism, and accident insurance. The financial side of this matter unquestionably needs especial care in this country, not only in its relation to physicians but in its general aspects, and particularly in justice to the insured, because our political morals are admittedly looser in this country than in England or Germany. One of the most successful ways of avoiding disagreements is through not forcing regulations but agreeing upon them; and the more largely arrangements are made with medical men through friendly understandings rather than as bargains, the more successful will they be. It would greatly help in avoiding contention and in establishing in wise form many of the details of the system in which medical advice is highly important, if the local medical men involved had direct representation on the governing bodies of these insurance companies if they come to be formed. Many other factors are tending to make medicine more important as a public profession, and relatively less so in a private relation in its main activities and emoluments. There is already a lessened demand for the family doctor because of the increasing control of infectious diseases. The methods that have done so much for the control of tuberculosis can do similar things in controlling the effects of alcohol and venereal diseases. With a decided drift toward the control of these enormously important causes of disease, a large effect upon the sum total of the doctor's repair work and upon his purely palliative treatment must be exerted. As a result of these tendencies the choice of a medical career, aside from the direct care of the sick, no longer means a distinct shifting of purpose and detachment of one's self from a medical career. The changed point of view is largely due to the change in the character of medical teaching and the increasing complexity of the study and practice of medicine. The higher standards have made many men feel that the standards of practice do not meet what they desire, and that in confining themselves to private practice they are taking a step downward in regard to thoroughness and accuracy of effort. This was probably due to the chasm that existed between the laboratory and the clinical branches of medicine. In order to bring the laboratory and the clinic on more intimate relations the essayist favors the plan of having a group of clinical teachers who practice little or not at all outside of hospitals.

3. **Cholecystostomy vs. Cholecystectomy.** — F. B. Lund refers to the lack of agreement among men of experience and skill as to the indications for cholecystectomy. He reviews the recognized advantages of cholecystostomy upon which surgeons are very well agreed, and believes that cholecystectomy is indicated in the following cases: 1. In cases of very thick, acutely inflamed, bright-red, or gangrenous gall-bladders due to impaction of a stone in the cystic duct. 2. In cases of chemically thickened gall-bladders. Here the thickened walls cannot contract and drive out the bile, so that what bile gets back into the gall-bladder is sure to stagnate there; after cholecystostomy, the walls do not contract, so that we get a mucous sinus for a long time or forever. 3. In cases of gall-bladders very much distended with clear fluid from impaction of a stone in the cystic duct. 4. Whenever suspicion exists of malignant disease. 5. In chronic cholecystitis without stones, but with moderate thickening and ulceration of the mucous membrane, giving little yellow spots on the mucous surfaces, the so-called "strawberry gall-bladder." These do not get well without drainage. 6. In chronic cholecystitis without stones, but with adhesions to the surrounding organs, especially the pylorus, which cripple the latter and cause symptoms. Here, also, drainage alone is only temporarily efficient. The gall-bladders is a constant focus for low-grade infections and adhesions, which will continue to form and

perhaps to spread until its removal, all these processes being attended with discomfort and invalidism to the possessor of the organ.

4. **Report of a Case of Sacroiliac Strain Following Symphyseotomy.**—Charles F. Painter reports this case because the question as to the existence of sacroiliac mobility has so often been raised. In thsi case there was evidence of hypermobility of the sacroiliac joints; this was associated with severe backache, and gave ocular evidence of its existence by the pronounced lipping of the sacroiliac joints, as shown by the *x*-ray. The writer says that it may be maintained that even though one admits the validity of the claim that motion in these joints is evidenced by the lipping of the bones making up the joint, this is due to the fact that there is no connection at the symphysis. There never is a bony connection, and though the abnormal separation in this patient may, and undoubtedly did, aggravate the already existing mobility, still there is abundant evidence that these joints are in existence and are subjected to the same diseases to which other joints of the body are subjected. No better evidence is needed than this proof of the existence of these joints; and if there are joints, motion must follow, in some degree at least. Such a case cannot be of very common occurrence, and goes to prove that the sacroiliac joints, though unlike other articulations, resemble them in their essential features.

8. Pathological Conditions in Hematuria and Pyuria. A. S. Sanders.

1. **The Value of Autoserum Injections in Skin Diseases.**—William S. Gottheil reviews the recent literature in reference to the use of autoserums in skin diseases and states that he has fairly complete records of thirty-one cases of psoriasis, nine cases of various forms of obstinate chronic eczema, seven cases of chronic urticaria, four cases of very bad pustular acne, five cases of furunculosis, five cases of pemphigus and eight cases of florid secondary syphilis, and several cases of chronic lichen planus, leprosy, and other chhronic affections. From his experience with these cases he concludes as follows: 1. In psoriasis the autoserum treatment, while not in itself curative of the disease, is an important factor in the treatment. It cuts down the time required for the troublesome local treatment from weeks to days, and enables us to promise to clear the skin in from two to five days in even the worst and most obstinate cases. It postpones relapses for a long time, possibly indefinitely. In most cases it so influences the type of the disease that the relapsing lesions are few and insignificant, and are readily amenable to mild local treatment. 2. In chronic urticaria, neurodermatitis, pruritus senilis, and other obstinate itchy dermatoses it is worthy of trial. In some cases its action is effective and brilliant. 3. It is of some value in bad pustular acne; but in furunculosis, folliculitis, and other pus infections I have not found it useful. 4. In chronic eczema the same may be said as of acne; the injections are sometimes apparently effective, and at others fail entirely. 5. In pemphigus, lepra, and obstinate lichen planus it is ineffective. 6. In syphilis it is useless.

3. **Nephritis in the Aged.**—I. L. Nascher says that the frequent autopsy findings of interstitial nephritis in senile cases which gave no symptoms of the disease during life, and the frequent diagnosis of interstitial nephritis in senile cases which do not show the pathological condition upon autopsy, force the conclusion that either the pathologist or the physician was careless or ignorant, or else that nephritis in the aged does not present the clinical history or the pathological features that we find in earlier life. We often get a symptom complex in an elderly person which in a younger individual would justify the diagnosis of interstitial nephritis, yet in an aged person every one of these symptoms may be due to a cause which is neither directly nor indirectly traceable to the kidneys. Senile contracted kidney with slightly diminished output of urine, of rather high specific gravity and a trace of albumin without casts, is a physiological condition. It requires no treatment, and efforts to increase the output may cause a mild irritation and inflammation, followed by degeneration of the glomeruli. Chronic interstitial nephritis is a pathological degeneration superimposed on a normal degeneration, and by extension it will involve the glomeruli, producing a diffused nephritis. Parenchymatous nephritis is always secondary, either to an acute nephritis or, by extension, to an interstitial nephritis. By extension it will become diffuse, involving the whole organ. Acute nephritis may be primary, following the ingestion of poisons or renal stimulants, or it may be secondary, the irritation arising from bacteria or products of autointoxication or metabolism. If mild it will pass into parenchymatous nephritis; if severe it is speedily fatal. All pathological degenerations hasten normal degenerations and are therefore incurable. In the severe form of acute nephritis, which is always fatal in the aged, the physician is justified in trying anything which might increase the output of urine. In one case of parenchymatous nephritis with suppression of urine, the author used sodium theobromine salicylate in 42-grain doses three times a day for several weeks. In this case the ordinary diuretics in the usual doses failed to increase the urinary output, but these large doses were effective.

7. **A Plea for Male Nurses.**—P. Samuel Stout presents the following arguments in favor of training young men to the nursing profession, and urges that an educational campaign be instituted in all the high schools informing young men of the advantages of taking up this profession and urges that all hospitals receiving State aid be open to them. He says that male nurses are necessary because of the increasing scarcity of female nurses. Male nurses are more fitted to the work in the male wards than female nurses. Male nurses could attend to all the orderly's duties with much more efficiency than the ordinary orderly. Male nurses could carry out all the operating room technique. Male nurses would become more and more proficient, since their work would be continued as a life work and marrying would not terminate their nursing careers as it does with the female nurse. Male nurses could be trained as professional anesthetists. Male nurses would have a good groundwork for the study of medicine and this would provide a good way for the ambitious man to work his way through medical college. A certain proportion of young men should be trained for nursing in army hospitals. In the event of war they would be invaluable, and could be sent to places where it would be impossible to send a female nurse.

1. **Further Reflections of a Medical Teacher.**—W. T. Councilman says that some years ago he gave an address of "Reflections of a Medical Teacher"; to-day his reflections follow along much the same lines, though the views expressed have in some cases undergone some alteration and repair, and in others have become deeper and stronger. In teaching, one is concerned (1) with the material, just as the farmer must consider first the character of the soil he tills. Continuing the agricultural simile we are (2) concerned with the tiller, his selection and training and his ability for his job. The (3) point is what sort of a crop he wishes to produce, and (4) what methods of culture he pursues. In private school teachers are selected rather on a basis of athletics and social qualifications than on the ability to train and inspire youth. The possession of a "Ph.D." is also regarded as one of the desirable qualifications of a teacher. The character of the work which the degree demands in no way qualifies him to teach. How much better it would be for him to spend the time under a competent master in the study and practical exercise of teaching. Every one engaged in the tillage of the soil must study its character. Harvard having required the A.B. degree as a condition for entrance into the medical school since 1900, so far as he has been able to learn by careful study of results, on the whole the A.B. men are better. The hereditary element also favors the college man. He has been greatly impressed with the evidence which college men often present of a lack of thoroughness in the instruction they have received. He believes that teaching is a calling which if engaged in should be the paramount interest in life, that it is a responsible, serious, and noble calling. Teaching should not be a bar to research, and many of the great teachers he had known have been both teachers and investigators. He thought it would be well if universities could be placed in a wilderness and withdrawn from the environments of idleness and wealth. Medical education must provide constant exercise in the study of disease and practice in methods. One of the most important elements should be the recognition of knowledge and its separation from conjecture. The lecture is an important part of teaching, provided its function is understood. It should be used to expand and coordinate the knowledge which the student has already acquired. Next to the lecture comes the demonstration, a method of overrated value. Oral recitation is also a valuable exercise provided it can be given in such a way as to bring out the conceptions which the student has formed and to correct those that are faulty. The profession of medicine is a career full of interest, the social position of medical men is on the whole good, there is a general feeling of fellowship and comaraderie among them, fostered by frequent meetings in societies.

2. **The Relation of Gout to Nephritis as Shown by the Urine Acid of the Blood.**—Morris S. Fine presents certain data which raise the questions: 1. Is gout merely a stage in the development of interstitial nephritis, whose further progress may be indefinitely delayed? 2. Is early interstitial nephritis merely potential gout, in which the clinical symptoms may or may not eventually appear? 3. Is the uric acid retention of gout due to a specific condition, *gout*, or to a complicating early interstitial nephritis. The two practical points brought out in the paper were these: (1) Since uric acid is the first of the nitrogenous substances to be retained in interstitial nephritis, its determination may give the first indication of this condition when other symptoms are uncertain or lacking. (2) Since gout and very early interstitial nephritis are characterized by essentially the same blood picture, it is necessary to employ every possible test to exclude nephritis before a high blood uric acid may be regarded as evidence of gout in the absence of the typical classical manifestations.

3. **The Treatment of Chronic Colon Bacillus Pyelitis by Pelvic Lavage.**—Herman Louis Kretschmer and Gred W. Gaarde said it was not their object to discuss the various forms of treatment advocated for pyelitis, but to present the results obtained by pelvic lavage in this series of cases. This series deals only with chronic colon pyelitis, and most of the patients had resisted medical management. As a routine, a 1 per cent. solution of silver nitrate was used. The amount injected varied from 5 to 7 cc. as an average. Great care should be taken to avoid a rapid filling of the pelvis and not to use too large amounts. In some of the cases, catheters were passed into the pelvis and, in others, only about one-half way. The treatments were carried out once every five or six days until the urine was sterile and free from pus. In summarizing the results of treatment they reported only on fourteen patients because they were able to follow this number to final results. Of the fourteen cases treated by lavage, bacteriological cures were obtained in eleven cases. In the remaining three it was possible to obtain positive cultures from the ureters, although subjective symptoms and leucocytes in the urine had long since disappeared. In four cases, one injection was given; in five cases, two injections; in three cases, three injections; in one case, four, and in another, eight injections. They drew the following conclusions: (1) From our results in this series of cases we believe that pelvic lavage gives a greater number of bacteriological cures in a shorter space of time than any other form of treatment. It is important that the urine be sterile in order to prevent recurrences. (2) In several instances we obtained sterile urine after one or two treatments of patients who had been on internal treatment for many months. (3) If patients fail to respond to this form of treatment we may be dealing with a condition other than a simple pyelitis, for example, tuberculosis, stone, or stricture of the ureter.

5. **Reactions Following Intraspinal Injections of Mercury.**—George W. Hall, Hayes Culbertson, and Carry Slaght give a summary of the work they have done in the Cook County Hospital, with intraspinal injections of mercurialized serum, mercuric chloride and mercuric succinmid. In fifteen cases treated the following symptoms were noted. Pain was rather severe, localized in the back and extending down the limbs in all of the cases. There was retention of the urine in two cases which lasted for twenty-four hours, requiring catheterization. The patients had no trouble after the first twenty-four hours. There were insomnia and restlessness in four cases. There were headache and pain extending down the back in ten cases. A rise in temperature ranging from 99 to 103 Fahr. was noted during the first twenty-four hours in all the cases. The temperature began to rise about four or five hours earlier following the injections of the mercuric chlorid and succinimid than following the injections of mercurialized serum. The cell count in the spinal fluid during the first twenty-four hours following injection ranged

from 300 to 2,000 cells per cubic millimeter. During this period the polymorphonuclear leucocytes predominated with a gradual return to the lymphocytosis later. The period of increased cell count lasted on an average about 72 hours. Some of the patients expressed a feeling of improvement a week or two after the injections, and requested further treatment, but no statement could yet be made as to the ultimate results following these injections. The writers recommend that in administering mercuric chloride 1/100 of a grain be used when using the spinal fluid as a vehicle. This can be made up in a 1 per cent. solution using 20 c.c. of spinal fluid as a vehicle.

1. On the Influence of Antiseptics on the Activities of Leucocytes and on the Healing of Wounds. — C. J. Bond has devised a method by which he uses an indigo thread placed in a wound which serves as a trap to catch emigrating leucocytes. In this way the cells can be recovered for microscopic examination at various interfals after operation, and the influence of various antiseptics can be observed on the behaviour of the leucocytes towards inert pigment particles, and albuminoid and other oryanic substances introduced into the wound. In this way the writer has made a considerable number of observations under strict aseptic conditions in the human subject, and many antiseptics in different degrees of concentration have been tested by this method of the decolorization of the indigo thread. The outcome of the inquiry seems to be that antiseptic solutions in moderate degrees of concentration exercise less influence over emigration and phagocytosis than many surgeons have supposed. There are, however, reasons for concluding that antiseptics do exert a considerable inhibitive effect on the return immigration of living phagocytes. This aspect of the subject should be borne in mind in descriptions of the effect of different antiseptics in killing off pathogenic organisms in pus and other liquids in vitro and on the sterilization of wounds. Provided efficient drainage is ensured, the surgical application of most antiseptic solutions does not apparently materially prejudice the defensive activity of the tissues in either infected or non-infected wounds. If it can be shown that the use of antiseptic reagents does at any stage inhibit the activities of the pathogenic organisms, then, although these reagents do undoubtedly cause the death of a certain number of body cells and prevent others from again reaching the tissues, this is a small matter if the invading organisms are at the same time materially diminished in numbers or in offensive capacity. The occasional death of even large numbers of phagocytes is well borne if time be given to make up the loss. The experimental introduction of pigmented particles into a wound also throws valuable light on wound infection. In a general way the transportation of the pigment follows the same routes and the same lines of least resistance as those traversed by infecting organisms. The same peculiarities are apparent in the permeation of tissues and organs by pigment granules. The liver, the spleen, the kidney and the brain each presents its own problem in emigration, phagocytosis, and return immigration. Bearing in mind that pigment particles are incapable of intrinsic movement, or multiplication, or growth, any transportation of pigment, insofar as it is not due to currents in the lymph or other fluids bathing the wound, must be due to the action of living cells. The writer points out that several side issues of considerable interest arise out of this problem of the return immigration of the phagocytes. Unless the ingested cocci and bacteria which are carried into the tissues by the phagocytes on their return journey are killed, or sufficiently attenuated to render them incapable of further growth, they may start into renewed activity on the death and disintegration of the cells which contain them. It is possible that some cases of recrudescent local sepsis may owe their origin to this cause.

5. An Investigation of the Best Methods of Destroying Lice and Other Body Vermin.—J. Parlane Kinlock discusses the various methods that have been employed for the purpose of destroying lice and other body vermin and concludes that, as Bacot has shown and as his own experiments also demonstrate, lice do not survive immersion in boiling water. Of the various insecticidal powders that have been tested the N. C. I. (naphthalene, creosote, iodoform) powder is the most destructive to lice. Naphthalene and creosote have each a strong insecticidal action. The insecticidal action of iodoform is feeble. Commercial naphthalene is more actively insecticidal than pure naphthalene and it appears that the lethal power of naphthalene for lice is dependent in great part on the presence of hydrocarbons and coal tar derivatives other than pure naphthalene. The immediate lethal effect of creosote when mixed with naphthalene is less than that of some other insecticide liquids, but the longer period during which creosote continues to act more than compensates for the initial disadvantage. In addition to its feeble insecticidal action, idoform greatly increases the adhesiveness of N. C. I. powder. The insecticidal power of naphthalene-creosote powders gradually diminishes when they are exposed in the open air. The moist nature of such powders precludes their being used successfully in perforated tins and it has not been possible to dry the powders and at the same time retain the moist volatile hydrocarbons and other coal tar derivatives in which the insecticidal effect mainly depends.

6. Treatment of Infected Wounds by Physiological Methods.—Almroth E. Wright criticises the traditional methods of treating wounds by a combination of antiseptics, incision, and mechanical drainage, because it fails to kill the infecting microbes and at the same time fails to give the organism opportunity for ridding itself of the infection. He says the treatment of septic war wounds divides itself into three therapeutic procedures. In the first we have to promote the destruction of the microbes which have been carried into the deeper tissues. We have to re-establish normal conditions in the tissues, resolving the infiltration in the walls of the wound, getting rid of infected sloughs, prevent the corruption of discharges, and inhibit microbic growth in the cavity of the wound. During the whole period occupied by these operations we have to be constantly on our guard to prevent active and passive movements which would propel bacteria along the lymphatics, and carry poisonous bacterial products into the blood. Second, when the physiological conditions of the deeper tissues have been restored and the wound has been rendered to naked eye inspection perfectly clean, the surface infection must be dealt with. Third as soon as this has been suppressed, or all but suppressed, attention must be given to promoting the processes of repair, bringing together the tissues, and covering over denuded surfaces. The ideal object of

physiological treatment is to give intelligent aid to the organism in combatting bacterial infection. Saline dressings supply a means for evoking in infected wounds certain requisite psychological reactions. Hypertonic salt solution will act as a lymphagogue, drawing out from the tissues lymph which has spent all its bactericidal energy, and drawing into the tissues from the blood stream lymph inimical to microbic growth. It brings into direct application upon leucicytes a hypertonic solution (what is in view here is a solution containing 5 per cent. salt), will disintegrate leucocytes, setting free the tryptic ferment they contain. Such a hypertonic salt solution will also exert a number of inhibitory actions. It will inhibit the action of the tryptic ferment set free in the wounds. It will inhibit coagulation and so prevent the sealing up of the orifices through which lymph pours into the wound. It will inhibit leucocytic immigration into and prevent phagocytosis in the cavity of the wound. It will inhibit microbic growth. The writer discusses in detail the various methods of using hypertonic salt solution in the different stages of wound infection and the indications which call for the redressing of wounds.

2. A Case of Acute Diabetes, with Comments, Especially with Reference to Acidosis.—Walter G. Smith records the main facts in a case of diabetes occurring in a boy of seven years, and makes it the basis of comments which he thinks justify the following propositions. There is no simple, direct test for oxybutyric acid at our disposal. Its detection can only be effected indirectly. Barium oxybutyric acid forms long, needle-shaped crystals whcih are doubly refracting. Neither oxybutyric acid nor acetone gives any color reaction with ferric chloride; oxybutyric acid has no reactions in common with acetoacetic acid. Hurtley's method for its quantitative determination by extraction with ether and estimation by titration is described by Plimmer. For acetoacetic acid three tests are available: Gerhardt's, Rothera's, and Riegler's acetoaceticacid. Acetone does not respond either to Gerhardt's or Riegler's test. Its reaction with Rothera's test is similar to that of acetoacetic acid, but is less sensitive. The sensitiveness of Rothera's test is increased by the addition of a solid ammonia salt, as the sulphate of chloride. The writer has confirmed the value of this modification. The amount of acetoacetic acid in urine is usually considerably greater than that of acetone, according to Plimmer from two to ten times as much. There are two sources of acetoacetic acid in the urine, namely, that which is preformed and that derived from intravesical decomposition of ovybutyric acid. There is no simple and reliable test at present known for the detection in urine of small amounts of acetone in association with acetoacetic acid. Many data published in connection with acetonuria are vitiated by ignorance of this fact. Rothera's test differentiates acetone from creatinin. Creatinin reacts with sodium nitroprusside and either liquor potassæ or liquor ammoniæ. Acetone reacts only with nitroprusside and liquor ammoniæ. The term acetone bodies is not a happy one, for it lays stress on the least important member of the triad. Since acetone alone is not infrequently met with in urine, perhaps it would be well to indicate that fact by the term acetonuria, and to use the term acetouria for the cases in which acetoacetic acid occur. The theory of acidosis is still incomplete. The modes of origin of "acetonuria" are complex and are largely influenced by the amount of carbohydrate food assimilated. There is no evidence that either oxybutyric acid or diacetic acid exercise any specific toxic action apart from their acidic character. At present all we are entitled to say is that coma may come about by disturbance of the normal delicate adjustment of acid and basic radicals in the blood and tissues without postulating an excess of hydrogen ions in the blood.

3. Treatment of Septic Wounds, with Special Reference to the Use of Salicylic Acid.—Louisa Garrett Anderson, Helen Chambers and Margaret Lacey have made observations on approximately 1000 cases of septic wounds treated in the wards and operation theaters of the Military Hospital, Endell Street, making large numbers of cultures to determine the bacterial growth in the wounds. From these observations they draw the following conclusions: 1. The bactericidal action of many of the so-called antiseptics when applied to septic wounds is negligible. 2. The majority of wounds heal without the application of an antiseptic, provided free drainage is supplied and dressings are changed frequently. Hypertonic saline, in so far as it aids physiological processes, is preferable to many so-called antiseptics. 3. A strong antiseptic, such as eusol, can sterilize the surface of a wound with which it comes in contact, and, if applied continuously, gives excellent results. 4. Salicylic acid applied in a suitable form can often save cases when other methods have failed. It is particularly useful when dressings cannot be repeated at frequent intervals. 5. In all cases where recovery is delayed and the effect of the reagents of doubtful value the treatment should be controlled by making repeated cultures from the wound surfaces.

4. On the Ill-Treatment of Genital Prolapse.—W. E. Fothergill states that some 600 plastic vaginal operations are done every year at St. Mary's Hospital, Manchester, and they are thus afforded an opportunity of observing the results of many futile operations, and suggests what he considers suitable operations for the common forms of genital prolapse, which are four in number. 1. In true prolapse or complete procidentia, the operator should excise most of the anterior vaginal wall with the front half of the vaginal roof. The cervix should also be removed if it is unhealthy or if the uterus is more than 3 inches long. The writer's method of combining anterior colporrhaphy with amputation of the cervix is useful. 2. Where the uterus is long and loose the cervix appears first at the vulva and vaginal roof is inverted from above downward around the elongated cervix. There is no cystocele. This is a form of prolapse seen in virgins and nulliparous as well as in parous women. The treatment is excision of the front half of the vaginal roof together with the cervix, leaving the uterus 3 inches long. 3. In cystocele the anterior vaginal wall is everted from below upwards as in true prolapsus, but the uterus retains its normal position. Here anterior colporrhaphy is indicated. 4. In rectocele the posterior vaginal wall is everted from below upwards and the anterior rectal wall is adherent to it. This form of prolapse is seen in parous women with torn perineum, but not in virgins or nulliparæ. In this form of prolapse most of the posterior vaginal wall must be removed, the best method being Professor A. Donald's colpoperineorrhaphy, which is done from above downard so as to combine the two operations.

Book Reviews.

HUMAN PHYSIOLOGY. By PROFESSOR LUIGI LUCIANI, Director of the Physiological Institute of the Royal University of Rome. Translated by FRANCES A. WELBY, with a preface by J. N. LANGLEY, F.R.S., Professor of Physiology in the University of Cambridge. In five volumes. Vol. III. Edited by GORDON M. HOLMES, M.D. Muscular and Nervous Systems. Price, $5.00. London: Macmillan & Co., Limited; New York: The Macmillan Company, 1915.

THE third volume of Luciani's Human Physiology deals with the muscular and nervous systems and phonation and articulation. The reader will find in this work a comprehensive, but by no means exhaustive (or exhausting), discussion of these various topics. The author's method is to give an historical sketch of the work which has been done in the past and of the different theories which have been held, and then to criticise and bring into their proper perspective the several points which have been under review. It is this feature which, combined with the author's erudition, places the work on a higher plane than that which is enjoyed by the average textbook. In its philosophic method and general style, the book reminds us of Sir Michael Foster's classical work which appeared about thirty years ago. Appended to each chapter is a selected bibliography which cannot fail to be of service and from which many a reader may learn of the work of Italian scientists which is not as well known as it should be. Of the ten chapters of which the volume consists, that on the mechanics of the locomotor apparatus is particularly valuable because it deals with a subject which is generally either neglected or omitted by writers on physiology. The chapter on phonation and articulation has been much abridged; the author's remarks on the singing voice and the speaking voice deserve a larger audience than they are likely to receive. The sympathetic system is discussed in a very brief chapter, but the author makes amends by referring to the previous volumes of this work and by the ample recognition of, and reference to, the labors of Gaskell, Langley, and others. Much of the pleasure experienced in reading the volume is due to the smooth and capable work of the translator.

DIAGNOSTICO DE LAS ENFERMEDADES DEL CORAZÓN. Por ANTONIO MUT, Jefe del Dispensario de Medicina general de Instituto Rubio. Segunda edición, corregida y aumentada. Price, 7.50 pesetas. Madrid: Hijos de Reus, 1915.

PERHAPS in no other branch of medicine have such signal advances been made during the past decade as in the study of the diseases of the heart. These advances are to be mainly attributed to two factors: first, the use of precise physical methods of recording the work of the heart and the condition of the cardiovascular apparatus as a whole; and second, bacteriological studies of the blood in cases of heart disease. Naturally, the greatest progress has been made along the lines of diagnosis. For this reason a volume, such as the one under review, that deals with the diagnosis of diseases of the heart in the light of the most recent investigations would comprise practically the entire subject of cardiac pathology and symptomatology. The student of this branch of medical science will find in the second revised and enlarged edition of the important work by Dr. Mut, a veritable digest of the most recent knowledge of the diseases of the heart. An idea of the extensive research upon which the text is based may be gleaned by looking over the bibliography of 90 pages at the end of the volume, the references comprising about 1,800, and all of these being contributions subsequent to the year 1908. The text of this work is divided into thirty chapters, which are headed as follows: Anatomy; Physiology; Subjective Symptoms; Methods of Physical Diagnosis; Percussion: Auscultation; Murmurs; Examination of the Arterial Pulse and Simple Sphygmography; Phlebography, Plethysmography, and Tachography; Cardiography; Radiology; Electrocardiography and Phonoscopy; Sphygmomanometry, Sphygmobolometry, and Viscosimetry; Arrhythmias and Sinus Arrhythmias; Extrasystole; Heart Block and Stokes-Adams Syndrome; Pulsus Alternans; Permanent Arrhythmia; Loss of Tonicity and Cardiac Insufficiency; Tachycardia; Bradycardia; Valvular Lesions, Aortic and Pulmonary; Lesions of Auriculoventricular Valves; Congenital Diseases of the Heart; Angina Pectoris; Endocarditis; Myocarditis; Pericarditis; The Heart in the Infections; Pregnancy and Heart Disease and the Effect of Chloroform Upon the Heart. This work may be recommended to any one capable of reading it as an eminently up-to-day treatise on the diagnosis of diseases of the heart.

OBSTETRICS. A Practical Text Book for Students and Practitioners. By EDWIN BRADFORD CRAGIN, A.B., A.M. (Hon.), M.D., F.A.C.S.; Professor of Obstetrics and Gynecology, College of Physicians and Surgeons, Columbia University, New York; Attending Obstetrician and Gynecologist to the Sloane Hospital for Women; Consulting Obstetrician to the City Maternity Hospital. Assisted by GEORGE H. RYDER, A.B., M.D., Instructor in Gynecology, College of Physicians and Surgeons, Columbia University, New York; Assistant Attending Obstetrician, Sloane Hospital for Women; Associate Surgeon, Women's Hospital, New York. Octavo, 858 pages, with 499 engravings and 13 plates. Cloth, $6.00 net. New York and Philadelphia: Lea & Febiger, 1915.

ANOTHER very excellent and readable book on obstetrics makes its appearance. The call for text-books of this type naturally depends upon the needs of the student body, graduate and undergraduate, who are pupils of the author; the former to refresh their memories of the Sloane technique, the latter to obtain instruction in the methods of their teacher. Based almost entirely upon the figures and results obtained by the methods of this one institution, it is a question whether the logical title of the book had not better have been, "The Practice of Sloane Maternity Obstetrics."

The statistics of the hospital are instructive, and though not based on as large a series of cases as those published by some other institutions in this country, are quite complete and compare very favorably with figures published both here and abroad. Grouped in one chapter they would make a valuable collection for reference. The sections on management of normal pregnancy, antepartum examination, management of normal delivery, ectopic gestation, pyelitis of pregnancy, fibroids complicating pregnancy and labor, management of lactation, and artificial feeding during the first month, have not been equaled in any recent work of similar scope.

The Freiburg technique of scopolamine narcosis is carefully detailed. From observation in a limited number of cases, the author concludes that the method has its advantages in selected cases in a hospital, but that it is inapplicable as a routine procedure in a large teaching institution with an active service, as the staff requirements are too great.

Pubiotomy is shown to be a competitor with cesarean section in the moderate degrees of pelvic contraction, but in view of the complications the author hesitates to recommend the operation. Vaginal cesarean is described as a valuable addition to our methods of delivery, but one not lightly to be undertaken, especially by a novice. In speaking of the relative value of the extraperitoneal and the Sänger cesarean section in infected cases, the author believes that the superiority of the extraperitoneal cesarean section over the Sänger incision followed by a hysterectomy after the removal of the child is still to be proved, and prefers the latter. Discussion of unsettled topics, such as the Abderhalden reaction and the morphine treatment of eclampsia, is avoided as far as possible. The presentation of etiology, prognosis, and methods of treatment is conservative throughout, and recommends the book especially to the undergraduate student.

NURSE INSTRUCTION FOR CIVIL SERVICE EXAMINATIONS. Covering Nurse, Trained Nurse, Hospital Nurse, Visiting Nurse, Field Nurse, Tuberculosis Nurse, School Nurse, Nurse's Assistant, Assistant Superintendent of Nurses, Head Nurse, Supervisory Nurse and Superintendent of Nurses. Answers to Examination Questions and 250 Specimen Questions. New York City, New York State, New Jersey, Chicago and Federal Services. Price, 50 cents. New York: Civil Service Chronicle, 1916.

THE contents of this pamphlet will be evident from the lengthy title page, transcribed above. Three sets of questions are answered, and these answers are the ones sent in by the candidates who obtained the highest marks in each case. Intending candidates can thus see how their answers will be graded by the examiners, and they may also observe that little eccentricities in spelling are not seriously objected to. Indeed, the questions are not entirely blameless in this matter. Most of the questions seem practical, and the pamphlet should prove of service to any nurse who is thinking of applying for a civil service position.

(Special Report to the MEDICAL RECORD.)

(*Concluded from page 39.*)

SECTION ON OBSTETRICS AND GYNECOLOGY.

Wednesday, June 15—Second Day.

Colonic Infections: Some Seldom Described Nonspecific Types.—Drs. J. M. LYNCH and W. L. MCFARLAND of New York presented this paper. They said that in experiments on animals there were shown to be certain fundamental principles bearing on surgery of the gastrointestinal tract. The rate of motion of the intestinal contents was shown to be in direct proportion to their toxicity. It was most rapid in the duodenum. This was important to the protective mechanism of the animal. Thus the acid reaction in the terminal ileum was protective in character and alimentary disease should be interpreted in the light of this knowledge. Digestion was shown to be a segmental process and inflammatory conditions were most frequently found in the caudad segment where there were great quantities of bacteria. Twenty-one cases of purulent infection of the colon had been studied by the writers, which appeared so severe that tuberculosis was suspected in many cases. There was severe diarrhea with early appearance of pus, blood and mucus. The proctoscopic picture was typical, the mucous membrane appearing lifted from the subjacent structures and being edematous and ulcerated. After recovery an atrophic appearance occurred. The lymphatics presented no change except inflammation. Bacteriological examination was disappointing and did not throw light on the condition, the normal flora of the intestinal tract apparently only being present. Conclusions were that the etiology was unknown, the infections being acute at first and becoming subacute or chronic. They were segmental in character, suggesting vasomotor origin. Cases should be early recognized as infections and treatment should be medical or surgical, depending upon the type. Ileostomy had given very favorable results in some cases, as in a patient who had gained 22 pounds in six weeks after ileostomy.

Dr. J. W. DRAPER of New York said he wanted to thank Dr. Lynch for this valuable paper. He had seen a number of these cases with the reader and could corroborate what he said. The involuntary system supplied many nerves of the colon which had cells in the stellate ganglion. The thirteenth thoracic supplied the ileocecal region very largely and might account for the reflex symptoms so often seen in the stomach in the course of clinical disease. In regard to ileostomy, which was the method of treatment suggested by Dr. Lynch in his paper, Dr. Lynch had been the first to recognize the usefulness of this treatment in these conditions. Like many methods in general therapeutic use it had been employed sporadically a number of years and sufficient time had elapsed to prove its value. The reason that this worked so well from the point of view of surgical physiology was that it conformed to the fixed rule that the stoma, to give relief, must be early rid of the inflammatory process in the gut. Ileostomy had immediate effect on the nervous and mental condition by reflex action upon the duodenal and jejunal glandular secretion. To this fact also might be traceable the deaths in high intestinal obstruction.

Dr. J. M. LYNCH said that he wanted to mention medical treatment. All cases except the very acute could be relieved, and it was well worth while to try permanganate of potash, 1/5000 and in some of the subacute cases they had obtained good results with one teaspoonful of peroxide of hydrogen to each pint of water.

Congenital Inflammation, Deformation, and Defunctionalization of the Caudad. Ileum and Colon.—Dr. J. R. EASTMAN of Indianapolis gave this paper. He first described the fetal colon which, he said, lay free in the abdominal cavity to the left with its mesentery in contact with the parietal layers of the peritoneum. Later fusion of the layers took place, becoming connective tissue, fused to the abdominal walls, as far as the medial border of the left psoas muscle. Fusion occasionally was excessive and angulation occurred as the result. The gut itself became fused to the abdominal wall causing stagnation of contents. Another fusion took place on the right side and firm transverse folds occurred, differing, however, from Jackson's membrane. The persistence of this infantile position of the sigmoid was often noted. Later the descending genital glands, the ovary and testicle in descent from their primitive position might cause deformity of the terminal ileum and operation on internal hernia often brought to light the persistence of a fetal fold. The folds thus causing angulation of the sigmoid to the left, by irregularities of embryonic fusion, could be broken up by gauze dissection, by simple wiping of the folds. Another point of irregular fusion was about the cecum and terminal ileum. Fusion here often caused a retrocecal or retroperitoneal appendix, the latter being caught between the fusing layers. Dr. Eastman here showed diagrams illustrating the various irregularities of fetal fusion and also illustrative of Jackson's membrane, which was always associated, he said, with chronic appendicitis, and which differed from engorgement of the ileocolic artery with a hyperemic peritoneum and terminal ileum. The Jackson's membrane was often confused in the minds of many with fused membranes, but it was an entirely different condition.

Dr. GOLDSPOHN of Chicago said that Dr. Eastman had mentioned the extraperitoneal appendix and that back of the cecum. Eight years ago he had operated on a patient, a young, vigorous man, who had an extraperitoneal appendix lying concealed within the small pelvis. He had an indurated mass felt distinctly one inch inward from the right border of the ileum, which was very painful. There was no induration beneath this, as was usual from a ruptured appendix. The diagnosis was very much confused by the fact that six days preceding that time, he had been injured by a wagon pole striking him above the symphisis pubis. Four days after the injury, however, he was not disabled and he called a doctor because he had fever, nausea, but no acceleration of the pulse. The doctor thought it was caused by trauma. Dr. Goldspohn thought at first that the omentum had become strangulated between the layers of the internal fold. Hernia was present opposite the transversalis fascia, but did not descend into the inguinal canal. Going inward one inch from the border of the crest of the ileum, the doctor found a small mass with about half a dram of pus distributed into different directions; the peritoneum had a blue appearance. Working down, extraperitoneally into the small pelvis, to the spermatic cord and vas deferens toward the bladder, he got to the bottom of the infected area and discovered a mass of gangrenous tissue, about as large as a man's thumb (3 inches) that could be distinctly gathered up and had a pedicle running upward. The appendix was not thought of. It was tied off and taken out of the cavity, and the cavity enlarged extraperitoneally. It was desired to see the condition inside of the peritoneum and it was cut into. There was some free fluid but the intestine was not distinctly inflamed. Not wishing to infect the peritoneum from the venomous looking connective tissue area, the cavity was packed. There was temperature for several days then it subsided. The patient made a satisfactory recovery.

Dr. GREGORY CONNELL of Oshkosh said he would like to express his appreciation of this masterly summing up by Dr. Eastman of the etiology of these conditions. In the past there had been two sources considered—inflammatory and congenital. In future the inflammatory could be ruled out. In corroboration of Dr. Eastman's point relative to the ileopelvic ligament of Lane, and also on the left side, he would like to mention an instance in which there was no inflammation in the abdomen at all but extreme ptosis and adhesions to the round ligament on the left side. The tube was not inflamed, but there was fusion with this ligament and the omentum. The division made by Dr. Eastman between the excessive fusion, demonstrated by the white line, and the vascularized layers, was a very important one and should be kept in mind to simplify discussion. He saw Dr. Jackson in the meeting and he hoped that they would get some explanation of the original picture of Jackson's membrane. As he understood it there was a difference; Dr. Jackson's membrane being a pericolitis, not a pericecolitis. He would like to hear from Dr. Eastman whether these conditions were a result or merely a coincidence. The treatment of the condition would rest upon that point.

Dr. J. M. LYNCH of New York said that he thought they were all very much indebted to Dr. Eastman for the very excellent paper, but he believed that the kernel

of the whole proposition was that there might be any of these congenital deformities; there was, in fact, no such thing as perfect fusion. Any two layers might become separated or delaminated and become adherent and cause deformity. He did not believe that in the ordinary healthy peritoneum this was harmful, because it was elastic. It was the subsequent inflammation which left fibrous connective tissue. He did not think it was necessary to operate unless there was a change from ordinary endothelium to connective tissue.

Dr. JACKSON of Kansas City said that he had considerable interest in this subject, since he had described what had since been named "Jackson's Membrane." There had, however, been many things called Jackson's membrane which were not so. When the structures were considered anatomically and embryologically it was found that there were many departures from the normal. Many of these were due to fusion, transpositions and different causes. He thought that there were two distinct types of conditions clinically, and clinical symptoms existed sometimes from congenital malformations alone. There were angulations which produced symptoms, and the removal of which mechanical difficulty relieved the patient. Many cases were relieved by cutting adventitious bands. On the other hand, he was inclined to believe with Dr. Lynch that there must be an added element, usually infection, which made a complication to the original condition. There were other cases, however, where correction of the mechanical imperfection did not relieve the patient. The patient must be treated for affection of the inside of the colon. In the cases of true pericolitis (Dr. Connell was correct in so naming them) the pericolitis never goes on to the colon. Where cases had trouble from absorption from the outer colon there occurred a sensitization in the portion where the absorption took place. These cases had either to be let alone, or one could risk another operation in the ascending colon.

Dr. J. R. EASTMAN said that with all respect to what Dr. Jackson had said he would like to say that he had seen 100 times, over the cecum and caput coli, a thin veil that he could move about quite freely. He believed that these anomalous membranes had been seen by most of the gentlemen present. He did not mean to say that these irregularities impaired the function of the colon in every case, but occasionally it was definitely associated with angulated fusion and with arrest of the procession of intestinal contents, in other words, stasis in that zone. It has been occasionally observed that the separation of this excessive fusion would permit relief of the stasis. This did not happen often, but it was known to occur. The simple wiping away of adhesions could restore function of the stasic distal descending colon and proximal sigmoid, now and then. Dr. Eastman said he had purposely omitted the discussion of associated mental states, as there was not sufficient time to go thoroughly into the matter. He had tried merely to bring this simple message—that there was such a thing as excessive fusion between the mesentery of the large intestine and abdominal peritoneum. This might extend around and across the normal muscle band, and such fusions might apparently interfere with the function of the intestine, and the fact should be borne in mind that in the case of an oblique vascular abdominal band and folds down to the internal abdominal ring, the appendix might become arrested between these laminæ of the large intestine, so that when the layers became obliterated the appendix occupied a retroperitoneal position. The apparent postnatal adhesions of the omentum might represent fusion of the great omentum at the hepatic flexure or the splenic flexure and might not represent adult pathology at all. He was greatly indebted to Dr. Jackson for telling them what Jackson's membrane was (he had never known before). He did not believe that any of them knew what membranous pericolitis was. He could not see any reason why that should be limited to the ascending colon. He could understand that torsion of the cecum might pull it over from the serosa, but this did not have the course Dr. Jackson described. He felt that you could not do much with a fresh separable membrane; it was like shifting smoke. Removal gave rise to new adhesions. He felt that this membrane was quite distinct from the engorgement of the ileocecal artery.

Anterior Parietal Implantation of the Colon for Ptosis.—Dr. CHARLES A. L. REED of Cincinnati said that it had long been axiomatic and fundamental to say that constipation was the cause of persistent ill health. It was, however, a new viewpoint to attribute many anemias, rheumatisms, digestive disorders, nervous diseases and kidney diseases to the effects of the toxic state originating in constipation. Constipation could be said to be related to any or all diseases which might be influenced by toxemia with resulting acidosis. Treatment, to be logical, must correct anatomical disturbances. Causes of ptosis of the colon were numerous: dilated ascending colon, atrophied transverse colon, angulation of splenic flexure, adhesions to the sigmoid, etc. Each of these were asosciated with structural change and must be corrected by physical means. Cases without serious distortion, and those which could be corrected by hygienic measures were not under consideration. Only those cases were considered in which the relationship could be demonstrated between the intestinal condition and the constitutional state. The idea was current that it was best to try every other treatment before surgery, but a condition that was obviously surgical from the start should not be subjected to delay in treatment. It was impossible in every case to restore the status quo ante to the intestine, some conditions defying functional restoration. Thus there were two classes of operation—radical and conservative. The former were resections, the latter plications, fixations, and pexies. There was a rational demand for some conservative measures, and for this reason the writer had devised the parietal implantation of the colon, using the properitoneal structures, which insured maximal support. To do this a median incison was first made from the umbilicus to the pubis, the viscera were explored and the adhesions broken up. The peritoneal margins were then approximated, and a liter of hygienic salt solution put into the cavity, and the wound closed by laminated chromic gut. Next the upper abdomen was explored, the patient being in the Trendellenberg position, and the gall bladder and appendix being examined. The incision was not extended through the peritoneum. Dr. Reed had done this opperation 226 times with parietal implantation, and of these 96 had been in conjunction with other operations. There was no death from the parietal implantation alone. There were two recurrences, one due to trauma. In 200 there was marked functional improvement. Increase in weight of from 30 to 60 pounds had followed in many cases and headaches, mental symptoms, rheumatisms, depending upon toxemia, had been overcome. Dr. Reed showed charts illustrating the steps of the operation.

Dr. F. H. MARTIN of Chicago said a few fundamentals should be emphasized: first, all displacements of the colon and stomach, shown by pictures, did not lead necessarily to serious symptoms; second, adhesions in the abdominal cavity did not necessarily indicate that there were pathological conditions to be relieved, in other words, they did not lead to symptoms. This was illustrated by pictures shown by Dr. Ochsner at the clinical congress in Boston, where there was disease but no symptoms. Surgeons could go into the abdomen every day and find adhesions which had not given rise to symptoms. There were often seen displacement of the organs causing kinks which held the viscera in disadvantageous positions which might interfere with function. How did nature seek to cure these difficulties? How did nature hang up the colon when the animal assumed the upright position? By peritoneal fusion. The colon rotated, and peritoneal fusions occurred. Therefore, if it was necessary to make a peg to hang up the peritoneal contents, that was done by nature, and that meant that few of those cases required operation. It was only where the viscera were caught in disadvantageous positions that readjustment was required. The advantage of pexy was that it allowed the parts to be restored to more normal position.

Dr. R. T. MORRIS of New York said that surgery was the brutal way of overcoming what the internist had overlooked. In dealing with these cases one had to consider two important features: first, the group of susceptible individuals predisposed to these conditions; second, the matter which had been overlooked by the profession, that of sensitization, allergy or anaphylaxis. Unless an elaborate analysis was made ruling out the peripheral irritations and focal infections, they would not decapitate the demon of the patient's ills by doing any one operation. The psychic feature had to be included. One might do almost any operation upon a patient with epilepsy and the patient would be better for months. If one reported the cases quickly enough, one had brilliant results. If one waited, one would postpone reporting results at all. The day would come when the profession would have the Cabot system and make a report as a lawyer would make a brief out for

his client. The consultant would group together the testimony of various specialists, relating to irritations, focal infections, and so forth, and deduce his conclusions. In some cases he would have relieved a precipitating factor, not a causative factor. In these cases the surgeon was dealing with precipitating factors, and his work was merely a therapeutic resource which assisted the general practitioner, as the giving of a dose of salts might assist him. The surgeon had to be relegated to the position of a therapeutic resource.

Dr. Emery Marvel of Atlantic City said he appreciated the work of Dr. Reed on the subject of stasis. They might well study what was the most susceptible portion of the intestinal tract to stasis. If one took no other means of instruction, one would conclude that the most susceptible portion was the cecum. Dr. Reed had mentioned inflation of the cecum. The condition was passed over as not worthy of further mention. Exception should be taken to that. If the pictures of Dr. Reed were followed, in cases where benefit had been obtained, each picture showed stasis in the cecum. Dr. Marvel said he had seen great benefit by reduction of the cecum. Anywhere where one took peritoneal covering of the bowel and coapted it together there would be distention. In studying the anatomy of the ascending colon and cecum there were found three bands of striæ, and if sutures were applied here they would not stretch. In the cecal pouch most of the distention was below the ileocecal valve, and the pouch had to be reduced by making sutures in the longitudinal direction and drawing them up. This was offered as a consideration to Dr. Reed when cutting bands of adhesions. If he would obliterate the pouch and reduce the caliber of the cecum, additional benefit would accrue.

Prevention of the Passage of Gas Following Operations on the Colon.—Dr. A. J. Ochsner of Chicago read this paper. He stated that aside from direct interference with the circulation of the colon due to injury to the vessels or to tension, there was no source of danger to the patient so great as that which came from obstruction to the passage of gas following the operation. Dr. Ochsner presented charts illustrating the various methods by which drainage could be supplied to the site of operation and by which it was made impossible for gas to accumulate above the operative area. Various methods were as follows: (1) placing of a drainage tube in the ileum to the abdominal wall after removal of the colon. The mortality in these cases had been reduced to a negligible fraction; (2) after the removal of the ascending colon and attaching of the ileum to the middle of the sigmoid flexure, the placing of a drainage tube to allow escape of gas from the ileum; (3) use of a Jacob's retention catheter to drain through the rectum into the ileum and flushing of the openings, to prevent gas and fecal accumulation; (4) where there was inactivity of the colon, attachment of the ileum to the upper portion of the rectum or lower portion of the sigmoid flexure, and application of the Murphy proctoclysis directly to the ileum, irrigation either from above or below; (5) a portion of colon removed, not being able to be attached; a buttonhole opening was made in the abdominal wall or opening to the ileum left open at the distal end; (6) excision of tumor of the sigmoid, leaving enough intestine to make an anastomosis; in this case the lumen of the lower segment was not sufficient to carry a large drainage tube, and a small tube was used; (7) resection of the large intestine between the sigmoid and rectum with insertion of a double drainage tube and fixation by a few stutures, thus providing drainage for the gas. The sutures would absorb and the wound would cauterize and heal itself. In carcinoma of the colon there was often enormous distention, and the incision should be large enough for the entire hand. Such patients were bad surgical risks. The obstruction had to be removed and the tube applied.

Radical Operations for the Cure of Cancer of the Second Half of the Large Intestine.—Dr. William J. Mayo of Rochester, Minn., gave this paper, which was read by Dr. Charles Mayo. The paper dealt with the number of operations (419) from Jan. 1, 1898, to Dec. 31, 1915, at the Mayo clinic for resections of the large intestine. The average mortality was 14.5 per cent. In 262 cases there was a five-year cure (54 per cent.), and a three-year cure in 67.5 per cent. of cases. In 184 cases the left half of the colon and splenic flexure was resected with an average mortality of 17 per cent. The right half of the colon was resected in 235 cases with an average mortality of 12.5 per cent., the difference being 5.5 per cent., and this was considered due to the less septic character of the liquid contents of the right half of the colon as compared with the more solid content of the left half of the colon and to the greater safety of ileocolostomy, as compared with the methods of union following resection of the left colon. The mortality estimate included patients dying in hospital without regard to the length of time death occurred after operation. The mortality of resections for cancer of the left half of the colon was based on an operability of 62 per cent.; that is, of 100 patients 62 were operated upon. With an operability of 25 per cent. there was a 5 per cent. mortality. There were permanent cures in 60 per cent. A high operability with high mortality and a low percentage of cures gave twice as many cures to the hundred patients as a low operability and a low mortality and high percentage of cures. This appeared a paradox, but a greater number of patients had been given a chance. In desperate cases the two-stage operation was considered the best for the patient. Metastases were often the cause of inoperability. The patient, however, sometimes had a long rest before the recurrence of the disease, and recent advance in technic had extended radical operation to advanced cancers. In conclusion patients with cancer of the second half of the colon should be given a chance. The results were shown to be better than in any other position except cancers of the lip and in the fundus of the uterus.

Intestinal Obstruction: Further Experimental Studies.—Dr. J. W. Draper of New York said that intestinal obstruction was a many-sided problem, important to the abdominal surgeon and to the surgical physiologist, and important to conservative surgery and medicine. Medicine had as yet failed to recognize that man was but a link in the chain of animal and vegetable life and the loosely defined syndrome known as autointoxication was of interest alike to the surgeon and surgical physiologist. This syndrome was associated with delay in passage of intestinal contents. The relief by ileostomy, mentioned by Lynch, could be ascribed more to biochemical results than to mechanical measures. Future progress in study would lie in considering the alimentary tract as a whole rather than as cut into arbitrary morphological divisions. Results in recent laboratory experiments on obstruction at different levels showed that animals died early in thoracic and esophageal obstruction. In ileo-obstruction animals apparently died under the influence of obstructed secretion, which had been thought to be of fundamental importance in causing death due to obstruction. The beginning and end of the tract where shown to have many points in common, the toxicity varying with the digestive power. It was believed that the toxin was not in the cell but was a product of abnormal activity. The cells were not toxic, but their secretions were. They apparently manufactured a substance deleterious to the body. In duodenally obstructed animals the incoagulable nitrogen was double in twelve hours to that in the controls. This might be of value in differential diagnosis. The cause of death in obstruction was not yet known but was apparently due to aberrant activity of the jejunum and obstructed cells. Autotoxemia in the human would be better understood when the cause of death in duodenally obstructed dogs was known.

The Superiority of the Right Side Artificial Anus.—Dr. John Young Brown of St. Louis gave this presentation. He said that in cases of neoplasms of the lower colon and rectum with history of chronic constipation it was necessary for the surgeon to decide a quick and safe method for relieving the patient after the acute condition had been relieved. The cases were usually inoperable from the rectal standpoint, although sometimes radical work could be done. In these cases an iliac anus, excluding entirely the large bowel, could be rapidly made, a cecostomy being done to relieve the tension. This measure excluded the current from the large bowel and the continuity of the bowel could be later restored, though this was most difficult in a left-sided operation. The possessor of an artificial anus was not to be envied, but he could be made comfortable and without odor by the right procedure. The iliac anus did away with adhesions which would follow a left-sided anus and with the relief of acute obstruction the large bowel could be prepared for later radical procedures when necessary. The right-sided anus enabled the worker to work under the best conditions, and its closure could be accomplished by simple and satisfactory measures.

Dr. J. M. Lynch of New York said that he was very glad to know that the profession were beginning to

recognize the value of ileostomy in surgery. This was a comparatively old operation. It was first done twenty years ago by an Italian physician, and there had been scattered references in the literature up to the present time. At the time Dr. Lynch had first performed this operation it was upon a physician and he had a multiple polyposis of the bowel. He had very severe infection and was incapacitated from work. The results of investigations on this case were read before the Gastroenterological Society at Baltimore in 1915. The patient was interested in the work upon him and he was turned over to Dr. Lusk at Cornell, but he got tired of being investigated as to sugar, although he would have been willing, he said, to have been investigated on beefsteak. He then went to Professor Mendel and was investigated as to the contents of the ileum, and Bradley of Wood's Hole investigated the enzyme output of the lower ileum and found very few enzymes. The most important lesson learned was that the patient with an ileostomy was very comfortable and could be of more use than the patient with a colostomy. Dr. Wm. J. Mayo examined the patient and was convinced that the operation was one of great value. The patient was now practising in New Haven and had gained forty pounds and refused to take the risk of having the anus closed. The polyposis had disappeared but he thought if the current were turned back he might have a return of the trouble. It was not necessary to perform colostomy with ileostomy. In another case, a woman, who had an obstruction at the lower end, a catheter was passed through the ileocecal sphincter. The colon was filled with water and the water remained in. The catheter was then passed through the ileocecal valve and the water tapped. There was no need in these cases to make a cecostomy which was just as difficult to close as an ileostomy.

Dr. J. S. Horsley of Richmond, Va., said that he had recently seen such an operation which had saved a patient's life. The patient had a multiple papilloma of the colon. It had become ulcerated and there was a discharge of blood and mucus. The operation was done under local anesthesia. He noticed Dr. Brown said he used the lower stump of the ileum. He thought this had a good many advantages. First it made an opening in the cecum and retained the ileocecal valve. If the flora of the large intestine had access to the small intestine there would be trouble. There would be protection by getting the ileum to close up the cecum and retaining the valve. If 12 inches were left from the ileocecal valve there would be stump enough to make a union with the ileum when it was necessary to reestablish the current and preserve the valve.

Dr. J. Y. Brown of St. Louis said that he did not do a cecostomy in these cases, but he simply inserted the tube into the gut through the ileocecal valve. There was rapid relief in the lower bowel after the upper bowel was relieved. Where this operation was done in a week or more one could irrigate through the tube in the large bowel and get a relaxation where the original obstruction was and clean out the bowel as well. It was almost impossible to arrive at a correct diagnosis in these cases. Dr. Crile had reported three or four cases he considered malignant, and after the gastroenterostomy was done, the condition cleared up. In the rectal cases it was necessary to get immediate relief with as little delay and as simple a method as possible. This method had been found absolutely invaluable in cases of this type.

Pelvic Infection in Women.—Dr. Thomas J. Watkins of Chicago read this paper. He said that the subject was a very large one and he would deal with some of the features of its pathology. The modern treatment of pelvic infections should be based on knowledge acquired in special and general infection and immunity. It had been changed in accordance with the appreciation of the systemic nature of infection. It was not truly a local disease and recovery was due to systemic immunization. In puerperal cases inflammatory exudate was largely accidental except in embolic infections or phlebitis; in the nonpuerperal state the condition was different, on account of the mode of extension of the infection, which was by continuity of tissue, involving the Fallopian tubes. The local reaction was a conservative process limiting the bacterial invasion. Presence of pus was not now, as formerly, considered indicative of immediate operation. Pus might be in reality an autogenous vaccine, according to the work of Vaughan, Jobling, Petersen and Lusk, who regarded inflammatory products simply as reactions from bacterial invasion. Chronic and acute infections should be differentiated. The acute infections were the result of conflict with invading bacteria and the chronic dealt with the residues resulting from this conflict. His aim now was to deal entirely with acute infection. The treatment, medical and surgical, in these cases was confined entirely to sustaining increase of body resistance. No remedy was of value apart from this consideration. The outdoor treatment was of much more value in these cases than it was in tuberculous cases, as the one disease was more acute than the other. Patients would sleep better and take twice as much food with outdoor treatment, and upon this the body resistance depended. In very acute cases of puerperal infection where leucopenia was present, blood transfusion was of great value. In regard to systemic immunity, suppurations in the pelvis became sterile more readily than in other parts of the body, due to active reactions in the pelvis. Thus practically all puerperal infections would be medically treated, and it had been found that since there was less surgical treatment, there was a lower morbidity. Nonpuerperal infections should be also treated medically since they had marked leucocytosis. Three operations might be cited: curettage, incision and drainage, and excision of infected parts. The first should be condemned as dangerous and unnecessary; the second should be practised in exceptional cases, but prolonged operations under deep anesthesia were condemned as lowering resistance; the third, excision, had a limited field, *i.e.* with infected degenerated fibroids, with twisted pedicles of tumors, with acute intestinal obstruction, and with acute appendicitis.

Results Following the Treatment of Pelvic Inflammatory Lesions by Surgical Measures.—Drs. J. G. Clark and C. C. Norris of Philadelphia presented this paper, which dealt with the tubal and gonococcal type of infection. It was stated that a few years ago, when a patient was brought to the hospital in an ambulance the surgeon did not know whether the tube or appendix was involved. Both were considered surgical cases, and both were promptly operated upon. It was recognized now that gonococcus was a slow infection and rarely produced peritonitis. Dr. Clark then showed lantern slides of tables showing percentages before and since 1910 of the results of conservative treatment, with about 71 per cent. cures. He felt that conservative treatment showed that mortality was less and morbidity better with this method. The employment of drainage was always prejudicial to the patient. He would criticise Dr. Coffey's recent articles on the treatment by quarantine pack, because, in the first place, gonococcus infection tended to quarantine itself; it did not tend to peritonitis nor produce infection extraneous to its site. He felt that Dr. Coffey would find that this pack would produce hernia of the intestine and adhesions, and he would be obliged to discontinue its use. The conservative treatment aimed at the preservation of the menstrual function rather than at the preservation of fecundity, which had usually been lost in gonococcal infection. In only two of their cases had there been subsequent pregnancy.

Thursday, June 15—Third Day.

The External Signs of Diagnosis of the Attitude of the Fetus in Utero.—Dr. E. Gustav Zinke of Cincinnati read this paper. He compared the former practice of obstetrics by ignorant midwives with the present practice in the hands of physicians. This was practically a new branch, and he felt that it was the duty of medical colleges to provide competent teachers of this art. A great many physicians were not familiar with the principles of obstetrics, and the ignorant physician was as dangerous as the ignorant midwife. The most neglected side of this art was obstetrical diagnosis. Questions to be answered were: Was the patient really pregnant? If so, how far was pregnancy advanced? Would the parturient tract admit the passage of a full-term child? Was the patient healthy? What was the attitude of the fetus *in utero* after the seventh calendar month of gestation? In regard to the first question, the diagnosis was doubtful when signs were indistinct, when the patient menstruated irregularly or had never menstruated, or when she was past the menopause. The advancement of pregnancy might be determined by the size of the uterus or by the calculation of the last period. Thirdly, a thorough vaginal examination would reveal sufficient evidence of pelvic deformity to indicate instrumental delivery. Fourthly, family history and physical examination would reveal presence of disease. Fifthly, the attitude of the fetus *in utero* was important in the last two lunar months of

pregnancy. In a patient of normal stature and attitude a child might be born in almost any posture at the seventh month, but at the end the position must be determined. The fetal attitude must be diagnosed by external examination. To do this it was necessary to map the abdomen into four quadrants, right upper and lower and left upper and lower. To discover evidences of a breech or vertex presentation careful notation of the movements of the fetal heart and of the fetal movements in regard to these quadrants and to the umbilicus should be made. In vertex presentations the fetal movements were in the region of the diaphragm. The head would always select the right oblique diameter, which was the largest. The second and fourth positions of the vertex were most common and the first and third least common. In breech presentations the dorso-anterior position was most favorable for the body of the fetus and the d.a.l. position for the head. The fetal heart was to the left and level with the umbilicus, the movements posterior and below the umbilicus and the head in the upper right abdominal quadrant.

Dr. MANTON of Detroit said he considered this paper very important, because he found that on an average not more than 50 per cent. of practitioners made a diagnosis of presentation or position in any way. It was a great deal easier to diagnose presentation and position by external abdominal palpation than it was to do so by vaginal touch. The majority of physicians arrived on the scene after labor had begun, when the pelvic bones had overlapped so that, especially in nervous patients, vaginal examination was extremely difficult. The personal equation entered very largely into diagnosis. He found that it did not make much difference how well a man was trained; if he was indifferent and negligent, and if he took confinement cases only as pot boilers, he would not in any instance make a correct diagnosis. He could cite a case of one of his students, a recent graduate, who was sent to assist in a case which he diagnosed as transverse presentation. When the case was seen it was found that the young doctor had not even done abdominal palpation and he had jumped to the conclusion of transverse presentation. It turned out to be a perfectly normal presentation. Any paper which would draw attention to these diagnostic points was exceedingly valuable, and Dr. Zinke had rendered great service by enumerating these features.

Dr. JOHN O. POLAK of Brooklyn said that he was very pleased to hear from Dr. Zinke on the subject of palpation. The importance of this subject could not be overestimated. The knowledge gained in antepartem examination in following the course of labor was extremely valuable. In ordinary cases one could follow the advance of the course of the head and the descent of the head through the pelvis with the hand; and also the fetal heart in its descent and approach to the median line. In Faber's clinic the movements of the fetal heart were followed and studied and the course of labor determined by the descent of the heart of the fetus. It was impressive to mark the descent of the fetal heart every half-hour during the course of labor and to have the student record his findings to show the direction of the anterior shoulder of the fetal heart as the head descended into the pelvis, and in that way to obtain a practical guide of the descent of the head. In regard to the cervix, the dilatation of the cervix was followed through the rectum, and most of the normal cases were conducted with no vaginal examination. The progress was followed by abdominal palpation and by using the fetal heart and the condition of the cervix by palpation as a guide.

Dr. YARROS of Chicago said that those of them who had medical students to teach eight months out of the year found themselves in a curious position. These features were the A B C of modern training, which had advanced on that formerly given. These things had to be pointed out to students day by day, and it was necessary, because they would not remember them in making examination. It was so with the profession: they would not use the knowledge they had. The A B C of modern teaching was of the highest importance. It was not that the doctor did not know the breech from the vertex; it was that he did not use his knowledge. One made a diagnosis only by using methods of diagnosis. In listening to the fetal heart sounds it was important to ask the mother where she felt the baby most of the time. In a moment she would reply on the right side more often. The small extremity would lie there. The fetal heart sounds, as mentioned by Dr. Polak, were of importance. The student must listen to them when he made his diagnosis. The examination per rectum as to how much dilatation there was seemed to puzzle students a good deal, but this was one of the important means of diagnosis to be taught them.

Dr. ZINKE said that it was impossible in a fifteen-minute paper to cover the subject entirely, as it involved so many points. He had had some misgivings in presenting such a paper to such a learned body as this, but he had met with so many sad and serious experiences in his consultation practice that he thought a paper on this subject would be timely and would bring these ideas anew before the profession. It illustrated the fact that, having risen to the heights of abdominal surgery yesterday, it was proper that they should descend to the more common ground of equally useful and important subjects to-day.

Posture in Obstetrics.—Dr. JAMES W. MARKOE of New York read this communication. In it he gave a brief history of the antiquity of the usage of chairs for the use of women in labor. These were in use in the most primitive tribes in Africa, were common in the Orient, and had been in use in European countries through the middle ages and down to the present day. In Holland this formed part of an outfit of a well-equipped bride in the last century. In 1909 Dr. Markoe had turned his attention to the study of posture in obstetrics and its effect in different stages of labor. With the introduction of forceps in labor the importance of this subject had been lost sight of. The obstetrician should endeavor to make the first stage as short as possible to spare suffering to the mother. It was his duty to teach the woman to make the best use of her pains. In the first stage of labor the chair would allow full dilatation to take place. It would also allow the expectant mother to rest as much as possible. A study of the text-books showed that the physician was not expected to bother with the patient until the second stage of labor. The primipara, however, did not know how to use her efforts. The use of the chair would be found to exert the pressure of the bag of waters to the best degree. The rule of use-with-discretion applied to the chair as to all other procedures, but Dr. Markoe had found that since he had used the chair he had had recourse to far fewer surgical procedures. It had been used with 282 primiparæ and 38 multiparæ. Dr. Markoe showed slides illustrating primitive and medieval chairs, and also an experimental chair designed by him, with movable footboard and back, and also the use of the ordinary rocking chair with certain support for the feet which could throw the axis of the uterus back.

Dr. R. W. HOLMES of Chicago said that it was an interesting thing that a man who was the head of one of the largest maternity services in the country should discuss the question of posture in labor. All the rest of the morning had been given to the grandstand stunts of obstetrics, but the most vitally important were these things that every man ought to know how to carry out. He was sorry that Dr. Markoe's paper did not go further into the field of posture, because it was so vitally important to obstetric work. The original chair was the position of the woman merely squatting. This was the most natural position of emptying of the pelvic contents. It brought the axis of the uterus more nearly into the axis of the pelvis, thereby bringing the descent of the head into the brim. That position of crouching often secured the same effect. The extreme lithotomy position gave the woman the same position that Dr. Markoe gave with his obstetric chair. He did not see, however, how the chair could be said to shorten labor if the average time was twenty hours and the time in the chair was two hours. Twilight sleep had not shortened labor materially either. It was, however, a more vitally important thing that patients in the early stages of labor should have the advantages of more convenient posture. Posture meant much in abnormal labor. It meant the minimizing of forces. Thus in oblique presentations, where the long axis of the baby was transverse to the long axis of the mother, the woman should be put on the left side, where the head was to the left, and the fundus would gravitate and carry with it the breech. It would be well for all to go further into the ramifications of the subject of posture in labor. If the studies made in Dr. Zinke's paper and in Dr. Markoe's paper were followed all the time they would all get somewhere. There would not be so much indiscriminate cesarean section and there would be an end of the pseudo science of obstetrics.

Dr. BACON of Chicago said he had not been in the habit of letting the patient be up and around the room, mainly because of the danger of contamination. The patient was put in a sterile bed and effort was made to keep her in a clean condition. The contamination from

the floor to the feet was avoided and walking around, for that reason, was discouraged. The use of the chair and letting the patient get out of bed would defeat perfectly sterile conditions. He would ask the doctor to answer this point. He had been somewhat in doubt as to the value of abdominal contractions in the first stage of labor. It was chiefly the uterine muscle that dilated the cervix, but the experience of Dr. Markoe would incline him to try this.

Dr. J. W. Lee of New York said that, of course, the most natural thing in our existence was to be born. It seemed wonderful after millions of years that there should be so much discussion on the most natural procedure that mankind could first resort to. There was one other that was inevitable, but this was the primary entrance to separate existence. In posture in labor nature asserted itself. The most primitive posture, as Dr. Markoe had brought out, was squatting. He wanted to make reference to that, because it had been his fortune to be among primitive people. Many years ago, when he was among the Indians, he knew of an Indian woman about to be confined. He told the husband that he would be glad to be of any assistance if he could. The Indian asked him how much he would give him. Dr. Lee said that he asked the man how much he wanted, and the husband said he wanted a dollar. Dr. Lee agreed to give him this sum and the man agreed to let Dr. Lee know quickly when the birth was to take place. Shortly after the man came running and they both went running back and arrived in time. The woman was in a squatting posture and she simply pulled the baby out of the pelvis, bit the cord in two and tied it, took some handfuls of grass and wiped off the blood, the placenta came away, and that was all there was to it. In advocating posture care had to be taken not to bring on undue contraction of the muscles of the uterus for fear of rupture, but posture stimulating the first stage of labor would save no end of trouble. Another question was how was one to manage asepsis. He had heard a great deal about antiseptic labor and he had seen many, many cases of so-called puerperal fever that followed the most up-to-date, scientific, elaborate sterilizing procedure. There was one other condition that he had observed. In his early days in the wilds he was called to attend upon a primipara. He knew very little of obstetrics. The woman was in labor and he was beginning to be very nervous. He washed his forceps and got ready. He had no assistance but an old Irish lady who he was convinced knew much more about the matter than he did. Presently the old lady asked, "Doctor, aren't you going to quill her?" He said yes, perhaps that had better be done. He did not know what it was, but he had confidence in the old lady. The old lady picked out a good sized goose quill and filled it with black snuff and put it to the patient's nose. The patient began to sneeze and in fifteen minutes the baby was born.

Dr. E. P. Davis of Philadelphia said that he recognized the value of posture as set forth by Dr. Markoe, and fully indorsed what he said concerning it. He would also call attention to the value of posture in prolapse of the cord when the knee chest posture and vaginal reposition of the cord were often successful. Voucher's position was also often of value in moderate pelvic contraction. Dr. Davis said he was for primitive remedies, and he had often prevented cesarean section in the production of labor, by resorting to the posture on the knees. If more people went upon their knees more often no harm would be done. Lincoln had said that often in political crises he was driven to his knees because he had nowhere else to go. This principle would prove of use in labor cases. In the maternity hospital in Philadelphia where the matron was a woman of experience and sense, the patients with moderately contracted pelves were often to be found scrubbing the stairs, in the kneeling posture and with vigorous use of the arms. Spontaneous deliveries were the rule, and cesarean section was rarely resorted to.

Dr. Zinke of Cincinnati said that it was not his intention to unduly prolong the discussion, but he would like to emphasize the sledge-hammer eloquence of his friend, Dr. Davis. The question was how were they going to prevent the necessity of performing cesarean sections and other operative procedures. They could not abandon the judgment of the obstetrician. There was no question, however, in his mind but that many of the obstetric operations were performed too often and without proper distinction, but at the same time they should go slow and not express themselves entirely condemnatory of procedures which had proven themselves of benefit to mankind. The doctrine of narrow pelves, scarcely of age, which it had taken 100 years to develop, and which had been amply tested in the hospitals of Europe within the past twenty years, gave this result, that the cases of labor with narrow pelves had given 80 per cent. spontaneous deliveries. Five per cent. of cases had cesarean section with a maternal mortality of less than 1 per cent. He would take occasion here to mention one symptom, sometimes encountered, that was the "ringerbandel" or ring contraction. It could be seen when the abdominal wall was exposed, running transversely or obliquely, and it was always a danger signal of rupture of the uterus. The lower segment became so excessively attenuated that there was always danger of rupture. No man would hesitate, when he saw this ring, to perform cesarean section or hebosteotomy as the case might be.

The Use of Chloroform in the First Stages of Labor.—Dr. I. L. Hill of New York said that the use of chloroform in obstetrics was formerly widespread, and accident was almost unknown, but that recently its use had been criticised, largely on account of its relationship to active degeneration of the liver cells. Some hospitals had given up its use on this account. More evidence, however, should be forthcoming, based on autopsy findings, as to chloroform poisoning in obstetrical cases, than had at present been produced. Careful search of the literature failed to show sufficient evidence for abandoning it, as 5000 chloroform anesthesias has been performed without death, and some of these in very protracted cases. The prejudice against chloroform seemed to have arisen largely on account of laboratory experiments on dogs, in which it was found that damage took place by liberation of hydrochloric acid with alkalis. On this account Dr. Hill had undertaken a series of experiments on animals under chloroform anesthesia. His conclusions were that these animal experiments were in no way comparable to human anesthesias, the animals being frightened and struggling for hours, and requiring excessive doses, whereas a woman in labor was suffering pain and anticipated relief, so that the force of suggestion was added to the procedure. Dr. Hill had found that combined with small doses of pituitrin good results had been obtained. There was no arbitrary rule for chloroform dosage; it was necessary when the patient was unequal to the suffering. A very little chloroform would secure tranquillity and cooperation of the patient. Neurotic patients were most amenable to suggestion in this respect.

Obstetric Surgery.—Dr. E. P. Davis of Philadelphia reviewed his subject from the standpoint of modern surgery and from his clinical experience. The scope of obstetric surgery had become a wide one. Operation was indicated in many complications, such as ectopic gestation, colon bacillus appendicular infection, pyosalpinx complicating pregnancy, rupture of the uterus, ovarian tumor, fibroid tumors. All of these were complicating problems. In soft myomata of the uterus one distinguished surgeon had said that he could not tell the difference from pregnancy, but to the obstetrician Hegar's sign should always be distinct. The question of tumors was difficult; when they were present one had to ask how long the woman could go on and still have a living child. The obstetrical surgeon had also to be a vaginal and abdominal surgeon, but in many cases the art of obstetrics had been lost and a surgical monstrosity substituted. In spontaneous labor the maternal mortality was but a fraction of one per cent, and that of the child was largely due to asphyxiation. Abdominal cesarean section was to be done only in carefully selected cases, the mortality for the mother was then low, and it was the safest way of delivering a living child. In delivery by the vaginal route the death rate was in proportion to the leaving by the surgeon of the uterus in good condition, well drained and contracted. The fetal mortality in these cases was in proportion to the distance of the head; when the head was well in sight it was 10 per cent., with floating head as much as 33 per cent. Clinical diagnosis was of far greater importance in all cases than laying too much stress on laboratory findings and centimeter measurements. There should be constant clinical diagnosis, and the obstetrician should perform operations, not the surgeon.

Dr. E. G. Zinke of Cincinnati said that practice was one thing and the exercise of good judgment was another. Lawson Tait had suggested cesarean section for placenta previa, and Dr. Zinke had treated the subject in his entrance essay before this society. When he had got through reading his paper, there had not

been a single assenting voice. He had been roundly arraigned and subsequently criticised in the journals, but to those who had studied the subject, it was clear that there was justification for cesarean section in certain conditions of placenta previa. Every case of placenta previa was a surgical one, and could be recognized before hemorrhage appeared and sent to the hospital to the care of a good surgeon.

Dr. JOHN O. POLAK of Brooklyn said that there was just one point in regard to Dr. Davis' paper that he would like to mention. The success of the obstetric surgeon depended, first, upon his ability to make a diagnosis; second, upon the training of the individual operator; third, upon asepsis. In regard to rupture of the uterus, the speaker said that in the work of Finley sixty-two collected cases had been reported with no rupture, except where there was definite morbidity; that is, infection of some type. Every labor case should be studied as to its diagnosis, measurements, and position, and every case should be given the aseptic test, abdominally, following rectal interpretation.

Meddlesome Midwifery in Renaissance.—Dr. DELEE of Chicago stated that in the census of 1914 10,518 women died in childbirth. That was estimated on two-thirds of the population of the United States, and probably, when one considered deaths due to after effects of childbirth, such as nephritis, endocardial disease, etc., it was very much higher. Probably there died annually in the United States 20,000 mothers, and the infant mortality was as high. The morbidity was also high; 4,654 women died of sepsis in 1914. In puerperal cases 15 per cent. had fever of some degree. Pelvic adhesions were frequent, and many patients came back with the same history of never having been well since the birth of the child. Lacerated cervix was more common than lacerated perineum because the accoucheur did not take sufficient care of the cervix, and infections of this part were frequent. Too many interferences with the natural processes were being practised, the efforts that nature employed to expel the child being the best ones and intended to insure slow dilatation of the passages and gradual advance of the fetus. The old time watching and waiting policy in labor had been replaced by a polypragmasia, every sort of reason being advanced for hastening the processes of nature, including that of saving time and sleep to the obstetrician! One of the most common evils was the attempt to cut short the period of dilatation, and overstretching frequently resulted in gynecological and urological disease. The misuse of twilight sleep and of gas and oxygen had resulted in increase of postpartem hemorrhage and forcing the parturient to make too early bearing-down efforts was a very common cause of procidentia uteri. It was desirable to save the levator ani from too rapid distention. If a desire for too rapid labor were curbed and an extra half hour given, it would save the woman from permanent relaxation of the pelvic floor. Other dangers were the use of pituitrin, which should be entirely condemned; too frequent cesarean section, and the use of cutting operations instead of natural dilatation of the cervix.

Dr. A. J. RONGY of New York said that he wished to emphasize the operation of pubiotomy in protracted labor. The use of forceps often precipitated infection, and pubiotomy was the only choice. After a woman had had two or three dead babies and was very anxious to have a living baby this operation would give her a chance. Cesarean section on the mothers gave a 30 per cent. mortality in the children. In placenta previa, at the seventh or eighth months of gestation when there was profuse bleeding with no signs of labor, the operation could be tried because one did not know when labor would take place. Another point was being able to diagnose the size of the baby in the uterus as this would decide whether induction of labor was desirable.

Dr. E. P. DAVIS of Philadelphia said that he had done eight pubiotomies, and he had stopped. He did not like the operation. He was in entire accord with Dr. Holmes in wishing to stop unnecessary cesarean section. He hoped he would be able to do it. To the modern obstetrician fell the task of repairing injuries of labor, the injuries to the cervix, the pelvic floor, and perineum. No vaginal operation was complete unless these points were attended to. With regard to the criticism of Dr. Bacon about intrauterine gauze drainage, he had never seen retention of lochia. He had seen 8 per cent. complete union and 10 per cent. partial union. In regard to rupture after cesarean section he had done a number and had not had rupture, but it was an emergency procedure. He was heartily in accord with Dr. DeLee's remarks that injury to the genital tract produced invalidism. He did not believe in curtailing labor. The question of palpation was important in diagnosis. A man should be able to tell when engagement was there or not there. In regard to sepsis, the woman did not die so much from the hemorrhage and sepsis as from changes in the liver and kidneys as the result of toxemia. In regard to his friends Drs. Carstens and Zinke, he asked what could he as a specialist do to make their practice better. He could send them recent graduates, men trained to give anesthesia properly, men who knew when the head was engaged and when to call in the older practitioner, men who knew how to watch the case. He wanted to give these men assistants who knew how to use modern facilities. These older men had fought out the problems single-handed, and the next generation had had the advantage of their knowledge. All honor to the old guard.

Dr. DELEE said that he wished to subscribe most heartily to the last words of Dr. Davis, and if the old guard would adopt the methods of the younger men, they would say all honor to the young guard, too. One important point was the rectal examination. It was a pity that it took so long for men to learn it. If everyone would try it out on his next case it would be astonishing how much would be accomplished. With external diagnosis and rectal examination one could get all the information necessary. Here he would say that chloroform was not necessary to the general practitioner. He had been a general practitioner, and he thought one could instruct the husband to give the patient ether as well as one could give chloroform. Ether was more bulky to carry, but the physician would have to carry much more paraphernalia if he was going to do modern obstetrical practice.

Umbilical Hernia and Lipectomy.—Dr. WALTER LATHROP of Hazleton, Pa., sketched the changes which took place in the umbilicus after birth, resulting in the formation of a firm fibrous scar. In hernias this was weakened and the abdominal wall might be involved. This condition was twelve times more frequent in women than in men. Repair by overlapping to secure firm fixation was the most useful operation and considerable help was obtained by lipectomy where the abdomen was large and pendulous. Lipectomy was an easy operation to accomplish and if postoperative instructions as to diet and exercise were followed the relief from excessive fat would last a long time. The chances of recurrence of hernia were very much lessened by lipectomy in very obese patients.

Sheet Rubber Superior to Gauze in Abdominal Operation.—Dr. J. W. KEEFE of Providence, R. I., said that as long as surgery remained an art sponges would be overlooked and left in the abdominal cavity. Even very experienced surgeons had had the misfortune to leave something in the abdominal cavity. The human element was always present in operating and it was easy to leave a foreign body in the wound. Many cases never came to autopsy and so the extent of these mistakes would never be known. The causes included a bad light, unfavorable position, profuse bleeding, and many cases had happened with extrauterine pregnancy, hernia, and bladder operations. Forceps had been found after four years and sponges after twelve. In one case where an appendix had been removed under local anesthesia and a sponge was left in, the patient sued the surgeon, who contended that the patient was looking on and was therefore responsible. The court, however, held the surgeon responsible. Very many devices had been adopted to prevent these accidents, such as counting the sponges, or tying the sponges to tapes. None of these answered all objections, for if the work of Yandall Henderson were correct, the covering of the intestine with gauze was responsible for the loss of CO_2 content of the blood. The intestine should be placed in a bag. The use of the rubber roll would obviate many difficulties. Part of it lay outside the wound. It was easy to clean and sterilize and it was less irritating to the tissues. The loss of the CO_2 content of the blood would be prevented. The relief of not having to keep count of the sponges would be immediately felt by the surgeon.

Indications for Cholecystostomy.—Dr. DONALD GUTHRIE of Sayre, Pa., gave this paper. He said that the recurrences after cholecystostomy were from 1 to 33 per cent. He had sent letters to a number of prominent surgeons requesting their opinion as to the comparative results in cholecystectomy and cholecystostomy. Some advised cholecystectomy for the prevention of systemic disease. Some thought that it was only indi-

cated in malignant disease. Others, Crile, Lilienthal, and Erdman, preferred cholecystectomy in most cases, as affording better drainage. Counterindications for cholecystectomy were inexperience of the operator, desperate condition of the patient, obesity of patient, perihepatic adhesions. Deaver, Mayo, and Crile advised against it in empyema of the gall bladder. The latter was to be treated by cholecystostomy followed by cholecystectomy. The mortality was variously estimated as being lower or higher than in cholecystostomy. Conclusions were that cholecystectomy was the better operation, but was more dangerous and required a skilled surgeon, and that empyema of the gall bladder was best treated by cholecystostomy and later by a second operation.

One Hundred Consecutive Cases of Fibromyomata Uteri Subjected to Operation. — Dr. S. E. TRACY of Philadelphia said a study of his cases led him to conclude that malignancy was more frequent than was generally believed. In his series if microscopical examination six months after operation revealed a good condition it was considered a cure. His cases showed 12 per cent. of malignancy, and this was in accord with the general statistics showing that cancer was on the increase (62 per cent. in 1900 as compared with 78 per cent. in 1915). The ages of his patients were from 23 to 72 years, and 88 per cent. were over 40 years of age; sixty-three were married, twenty-seven single, and 72 per cent. had had children. In fifty-six cases there were associated abdominal lesions. After hysterectomy the amount of suffering from artificial menopause was noted. There was none in 18 per cent. of cases, other cases had varying degree, and in four it was very marked. Forty-eight patients had both ovaries removed. In these cases menopause symptoms were absent in 70 per cent. In women under forty years of age it was found preferable to leave the right ovary, but not unless it was absolutely normal. After forty years of age this did not matter. Fifteen myomectomies had been done. Of all patients two had hemorrhages postoperative, one controlled by *x*-ray. Seventy-four were alive and in good health, mortality was 2 per cent. He believed that all cases of fibromyomata uteri should receive early surgical treatment, and that those surgeons who advised women to do nothing but to await the menopause assumed a very serious responsibility. His list of operations included supravaginal hysterectomies 64; panhysterectomies 20; vaginal hysterectomy 1; abdominal myomectomies 9; vaginal myomectomies 6.

Operative Treatment of Fibromyomatous Uterine Tumors.—Dr. JOHN B. DEAVER of Philadelphia read this paper. He stated that much harm could be done by delay in the treatment of uterine tumors. It was claimed that diminution of tumor growth had been brought about by the *x*-ray and even more extensive claims were made for radium therapy. He felt, however, that while it was possible for radiation to check hemorrhage and influence tumor growth that this therapy excited false hopes and should be considered as malpractice. Radium should only be employed when operation was counterindicated. There was a large class of associated lesions in these cases, such as pyosalpinx, carcinoma of the appendix; ovarian cysts, dermoid; papillitis of the rectum or ovary; cholecystitis; hernia and other conditions. Surgery was the only safe treatment for malignant disease and the only way to cure cancer was to operate before it became cancer. The operation of choice was supravaginal amputation, and in some cases myomectomy. There was one other operation that might occasionally be of use, that was hysterotomy. Occasionally it was impossible to distinguish between pregnancy and a tumor symmetrically enlarged. Richardson had said in this connection that he could not always tell pregnancy when he had the uterus in his hand and the obstetrician could not tell when he was on the outside.

Recent Progress in the Surgical Treatment of Uterine Cancer.—Dr. J. J. JACOBSON of Toledo, Ohio, read this paper. He said that the criterion of cure in all of his studies was based on the five-year period. The radical operation of Wertheim had given 42.5 per cent. of cures for less periods of time and 25 per cent. of cases passed the five-year limit. Cases of recurrence after operation had usually been generally considered hopeless, but Zweifel had reported 30 per cent. of cures after 7.5 years for operation and recurrences. The treatment of Percy by diffusion of low-degree heat throughout the cancer mass was found, when properly performed, to raise the operability of cases to 90 per cent. *X*-ray and radium therapy were undoubtedly powerful agents in aiding in the cure of these diseases, as inoperable cases could be brought into such condition as to present a good operating field for the surgeon. The best results could then be obtained in the radical abdominal operation. Cancer of the uterus should receive the same treatment as cancer in other parts of the body and undergo radical operation. The type of cancer present should be determined and cancers of the vaginal portion of the uterus should be radically treated. The treatment by *x*-ray and radium should be restricted to inoperable cases, and these agents should also be used as a subsequent therapeutic measure following every operation for uterine cancer. In this way the patient would have been given the best possible chance against recurrence.

Dr. HENRY T. BYFORD of Chicago said that anyone coming there to-day would receive the impression that there was no other treatment for fibroid tumors but operation, but he had read a statement from the other side of the water that no fibroid tumors should be removed at all until radium and *x*-ray treatment had been tried. The truth did not lie with either extreme. Knowing that there was a certain mortality with some of these cases, he thought that there should be a certain amount of individualism in certain doubtful cases. With regard to *x*-ray treatment, it had the place which removal of the ovaries once had. It was found that the bleeding depended largely upon menstrual influence and that the congestion made the tumors grow faster. Removal of the ovaries stopped the hemorrhage and diminished the growth, and some apparently gave no trouble. This method had been abandoned after thorough trial. The *x*-ray worked the same way, but one could not get the *x*-ray into the tissue without destroying the surrounding tissue. If one restricted the cancer cells with fibroid tissue there might also be dessication of muscular tissue and the subsequent round cell infiltration would increase the trouble rather than diminish it. In certain cases there was no excuse for *x*-ray therapy, and this held true also of radium. It could not go through large tumors without also destroying the mucous membrane. Large tumors could not be treated in this way, but there should be a certain individualization in the cases of younger women with small tumors. The removal of the ovaries in the case of young married women who were to live with their husbands condemned them to a life of unhappiness. The social side of this question had to be considered, for although the woman and man stayed together on account of children a great deal of unhappiness was bound to result. The cure by removal of the ovaries was a doubtful one in any case. The removal of small tumors after the menopause was a more difficult matter, as a larger incision was necessary, and one had to go further into the uterus and one ran therefore more chance of sepsis.

Dr. CARSTENS of Detroit said he agreed with Dr. Jacobson on general principles, but one point was essential, and that was that one must make an early diagnosis. Cancer had a beginning and was so small at first that it could not be seen, but it would get in time to be as large as one's head. In older women it could be recognized. What was wanted was early diagnosis. Hundreds of women were curetted and no one ever took the trouble to examine the curettings, but they were thrown into the slop pail. Every curetting should be examined, and in one hundred cases these might be nothing but in the hundred and first case one would catch the indications. It mattered not whether the woman was nineteen or forty, it had been found at all ages. He said perhaps he was dull of comprehension, but when he heard his *x*-ray friends talk about getting cancer by exposure to the *x*-ray he wondered why did they use it to cure cancer. All these treatments came and went, and he could remember when his friend Marcy was experimenting with 200-ampere electricity; but surgery stayed with them forever. In regard to the other conditions, he agreed with every thing that had been said; especially did he agree with Dr. Deaver in regard to the operation on uterine fibroids. There was, however, one point he would make, and that was that fibroids did not kill the patient immediately. The surgeon should endeavor to get the patient into the best possible condition; and after due preparation, and when the woman was in the proper phase, operation could be done as soon as possible. In reply to Dr. Deaver he was surprised to hear the doctor advocating such an operation as hysterotomy. Personally he had always been able to diagnose pregnancy without cutting into the uterus, but if there was any doubt in the doc-

tor's mind it was easy to have an *x*-ray picture taken of the uterus; if the woman was pregnant the fetal bones would be shown. This was an easy procedure, and he asked the doctor not to do any more hysterotomies.

Dr. H. O. MARCY of Boston said that he remembered when he was experimenting with Apostoli's electrical treatment and he had asked him to come to his hospital in Boston and give treatments. The singular thing was that every patient believed that she was benefited by it. He thought that the *x*-ray and radium would follow the other treatment. What was there then left for the profession to do? He would advise them to follow Dr. Deaver, but he would say that if one was in doubt an *x*-ray picture should be taken and studied and one could find out what was in the uterus. Surgery was the only treatment to be considered, but he would ask the profession to make themselves more perfect in the technique so that they could do better work in the future than they, the older men, had done in the past.

Dr. HENRY SCHMITZ of Chicago said that personally he could subscribe to the last part of the last speech. He had done a great deal of investigation with the *x*-ray and with radium, and the question in his mind was whether all the statements of Drs. Jacobson and Deaver were correct, and he believed that they were not. Cancer was operable or it was inoperable. When it was operable it was a surgical condition, but when it was inoperable what was there to be done? There was the use of radium or the *x*-ray, or there was Percy heat treatment. Radium was indicated when the condition was entirely inoperable. The condition became operable under the use of radium. When the local condition was cleaned up the surgeon could then remove the uterus. Not every case of myoma was operable. The patient would probably have an advanced anemia or the myoma was probably advanced. It would be wrong to let the patient go as an inoperable case. Here the treatment by *x*-ray or radium was of much benefit. The treatment itself was easy, the patient was not required to stay in bed, it could be used under all circumstances, and the benefits were real and marked. Later the condition had been so much improved that it was operable, and it could then be treated surgically.

Dr. LAWRENCE of Philadelphia said that he simply wanted to emphasize everything that Dr. Deaver had said, but he wanted to add that the man who advised a woman with a neoplasm to let it alone should be dealt with very severely. Any neoplasm might become malignant, and many of them did. Out of 100 cases of fibroids 14 became malignant carcinomas. The mortality of hysterectomy for fibroids should not be larger than for ovarian cystectomy. There was little shock and the hemorrhage should be absolutely nothing. The tumor should be delivered out of the abdomen and grasped by a ligature about the base, and an oval-shaped incision sholud be made. By cutting out the tumor and tying the ligature one lost no blood unless there was venous blood in the tumor. In supravaginal hysterectomy one shoudl leave a convex pelvic roof instead of a concave one.

Dr. J. W. LEE of New York said that the subject was a large and interesting one. A great deal of time could be spent discussing the pros and cons, and it left them in the state of mind of the young man who came out of court and said, "I believe in the last speaker." Dr. Deaver had presented a paper that took in the whole subject. It might be called a classic. His paper covered all that had been said, and even included what Dr. Schmitz had said, because Dr. Deaver would not discard the use of radium in inoperable cases. Dr. Lee said he had been watching this fibroid game for thirty-five years. It used to be the custom to give large doses of ergot, and then Apostoli's treatment was considered a great success. He had been foolish enough to buy the apparatus, but he had never been able to sell it. Then came the fashion for oophorectomy. Then an abdominal incision was made and the uterus was brought out with four clamps and left, and one could see the stump rot. Then there was hysterectomy. In regard to the method of Dr. Lawrence, he must have fibromas and myomas made to order. It was generally necessary to go in further than he had described. He believed very strongly in the work done by Dr. Deaver, and he hoped that the style would not be altered in the next ten years.

Dr. ECCLES of Milwaukee, Wis., said that in their enthusiasm to cut something out he thought they were apt to overlook the operation of myomectomy. He granted that this was not indicated in the majority of cases, but in a young woman desirous of having children, or at least to menstruate, and where the tumor was not big, there was an indication for this operation. In his student days he had been taught that myomectomy was more dangerous than hysterectomy. In his experience this was not so. A considerable number of myomectomies had convinced him that the indications for myomectomy were often overlooked. In one case the patient was a young woman, the wife of a prominent physician, and she was unable to bear children, as she always aborted because of multiple fibroids. In this case a myomectomy was performed and seven or eight tumors were removed. The woman was now the mother of a four months' old baby and there was no recurrence. Even supposing such a tumor did return, the operation of hysterectomy could be later performed and the danger had not been increased.

Dr. RUBEN of Pittsburgh, Pa., said that it would be unjustifiable to leave this discussion with a little defense for the progress of medicine. If *x*-ray and radium treatment of malignant disease of the uterus could be considered malpractice, then all new ideas must be considered malpractice. In the old time ideal of curing cancer by the *x*-ray many men sacrificed their lives in the hope of contributing to the advance of medicine. This was due to their ignorance of the agent with which they were dealing. Now it was known that the rays were of different power—the soft, the medium, and the hard ray. In the old days the rays went through the hand, and men were burned and would probably later die of cancer. But at the present time men were shielded from the rays, and they did not carry radium around without proper protection. The rays were filtered, and the patients were given doses measured by radiometers. Patients were given 1/40 of a grain of strychnine, not 5 grains, and *x*-ray dosage was also according to measure. There were many young men, trained gynecologists, at the present day, who were watching this work and its effect on the growth of tumors, and when it was found that the *x*-ray was not having effect, then surgery could be resorted to.

Dr. S. E. TRACY of Philadelphia said that he did not believe that all fibroid tumors should be treated by surgery. He agreed with Dr. Schmitz that cases not suitable for surgery should be treated by the *x*-ray, but he believed that in malignancy an early diagnosis and a radical operation gave the best results. However, after all that could be done by surgery had been done, the patients should have the benefit of the *x*-ray. He did not believe that any case was cured by removal of the ovaries. A fibroid tumor without symptoms in a woman under forty should be left alone; after that the danger increased with the age of the patient. He believed that all curettings should be examined and not thrown away. He had never seen cases where he was afraid to operate for fibrosis. He had found it a good plan to spend time in getting the patient into good shape, and then operation could be successfully done. In this the *x*-ray was helpful for the operability of cases could be increased. Dr. Lawrence had spoken of his method, and he felt with the other gentlemen that Dr. Lawrences' cases were made to order. In all hysterectomies he found it a good plan to stitch the infundibular and pelvic ligaments to the stump and to pull the bladder back. It took three stitches. In regard to Dr. Eccles' remark on myomectomy, the age at which degeneration was likely to occur should be considered. After forty, this operation was dangerous.

Dr. J. H. JACOBSON of Pittsburgh said that he agreed with Drs. Schmitz and Tracy in advocating combined treatment. He was glad to hear that Dr. Schmitz advocated surgery in advanced cases. As a rule men who had done much along this line of work were apt to deprecate surgery. He believed that in radium, *x*-ray, and also Percy's heat treatment the profession had very powerful agents to assist them in radical therapy.

Non-Inheritance of Acquired Characters.—Our belief that acquired characters can be inherited rests very largely on some old experiments of Brown-Séquard on guinea pigs. These involved injuries of the nerve substance of breeding animals said to reappear in their progeny. Even at the time it was pointed out that sources of fallacy were present. In 1907 Wrzosek and Maciesza began to repeat the experiments, and their work was still in progress when the war put a stop to it. From the first it was apparent that there was no transmission of acquired alterations.—*The Journal of Heredity.*

RECENT PROGRESS IN THE OPERATIVE TREATMENT OF EMPYEMA OF THE THORAX.*

BY HOWARD LILIENTHAL, M.D., F.A.C.S.,
NEW YORK,
ATTENDING SURGEON TO MT. SINAI AND BELLEVUE HOSPITALS,
AND
MARTIN W. WARE, M.D.,
NEW YORK,
ADJUNCT SURGEON, MT. SINAI HOSPITAL.

FOR years the primary treatment of empyema of the thorax has been neglected. The cut and dried methods of past decades with an appalling mortality have gone on with practically no improvement because of lack of investigating interest on the part of the surgeon and because practitioners were apparently satisfied that when an opening had been made in the chest there was, for the time being, nothing else to do.

In nearly one-fourth of the cases the wounds required revision and frequently the patients were turned over to the surgeon for various deforming thoracoplastic operations.

The original cause of the pyothorax did not seem to matter—whether postpneumonic, metastatic, or primarily pleuritic—the treatment was the same. The patient was kept under observation and punctured until pus was found; an opening was made for drainage and the case was too often left to shift for itself. In the simple and unilocular cases in older subjects promptly operated upon there were many recoveries, but the least complication upset everything. When pockets or secondary isolated collections formed it was hoped that they might break into the main cavity and occasionally they did, but sometimes there was perforation into a bronchus, or the surgeon after many days and much puncturing averted this calamity, the patient meantime suffering all the dangers of sepsis.

A little more than two years ago the First Surgical Service at Mt. Sinai Hospital† took up the study of empyema with a view to developing a line of treatment commensurate with the therapy of infectious processes in other parts of the body.

We began with the assumption that the empyema problem was a pathological and a physiological one and not merely a matter of the mechanical emptying of a cavity from the most suitable point. The behavior of the diseased tissues of the living body had to be considered. We were aware that the causes which originally produced the empyema might still be operative after the chest had been opened and even that new conditions might arise after the operation to prevent a return to the normal.

Accordingly, we planned the therapy with two objects in view. First, the relief of intrathoracic pressure which immediately threatened life and, second, the establishment of a state which should make possible a complete recovery with a minimum of complications and without deformity.

Now, after two years of work and observation we hope and believe that we may report progress.

Our mortality rate is lower than that of the previous ten years in the same institution* and we have succeeded in preventing the necessity for a single thoracoplastic operation. We ourselves were responsible for many of the failures in the decade just mentioned and this fact appears to demonstrate all the better that the improvement in statistics may fairly be ascribed to changes in the methods.

We believe, too, that we have shortened the number of hospital days per patient by nearly one-third.

General Management of the Cases: X-ray. With few exceptions all our patients were examined with the aid of the Roentgen plate or screen, and we have found this of incalculable value in selecting the type of operation. Also, some interesting observations have been made in the course of these radiographic studies. We have found that in the encapsulated cases and also in the more chronic general empyemata the affected side is apt to show contraction of the chest instead of distention, the ribs being closer together than on the healthy side. This appearance has often been accompanied by the presence of tough peripleuritic confining membranes so that at operation the lung did not expand and required mobilization by the division or removal of the exudate.

Encapsulation is often beautifully demonstrated so that the most favorable point for drainage can be determined before the operation. We have found (Case 1, F. B.) two distinct sacs containing pus of different appearance and consistency which would have been overlooked without the *x*-ray. Secondary collections of pus have been demonstrated after the first operation and we have been able to empty these sacs promptly because of the accuracy of their localization. In two cases the secondary abscess was in front, on the right side close to the mediastinum near the base of the heart (See Fig. 5). They were evacuated from the front with the greatest ease and precision.

During convalescence the degree of pneumothorax can be made out and its gradual disappearance observed. The presence of areas of consolidation can sometimes be determined in cases in which there is

*Read May 16, 1916, before the Surgical Section of the New York State Medical Association, at Saratoga Springs, N. Y.

†The operations in this series were performed by Dr. Lilienthal, Dr. Joseph Wiener, Dr. Martin W. Ware, and a few by the House Surgeon under supervision.

*Wilensky, Abraham O.: *Surg. Gyn. and Obst.*, May, 1915.

doubt between residual empyema and pneumonia. Without the Roentgenogram unnecessary and possibly dangerous punctures would have been made. In two instances the *x*-ray enabled the diagnosis of foreign body in the lung or trachea to be made when

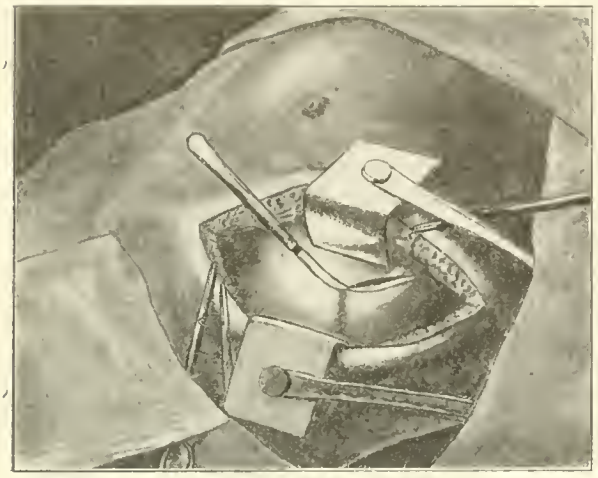

FIG. 1.—The chest is open, the rib spreader in place. The scalpel is making the incision through the layer of dense exudate which confines the lung.

clinically the case appeared to be one of atypical empyema. These patients were bronchoscoped by Dr. Yankauer and the foreign bodies removed. In one case pneumonia and pneumothorax were demonstrated after puncture made outside the hospital had yielded a few drops of pus, the patient being admitted for the treatment of empyema. There was no empyema and the patient recovered without thoracotomy.

We do not believe that this little list comprises all of the possibilities of *x*-ray diagnosis in empyema. And we have not here gone into the question of intrapulmonary disease.

Diagnostic Puncture.—After study of the physical signs and the radiograph the final proof, that of the aspirating needle, should not be made until the patient is on the operating table or within a few hours of operation. Repeated puncture several days before the operation may do harm. For example, some of our cases suffered from spreading infection of the tissue planes of the thoracic wall as the result of needle punctures. This, to be sure, is often a danger avoidable by early operation and by Roentgenography before the aspiration. The danger of puncture is much greater in lung abscess in which we believe it is absolutely contraindicated.

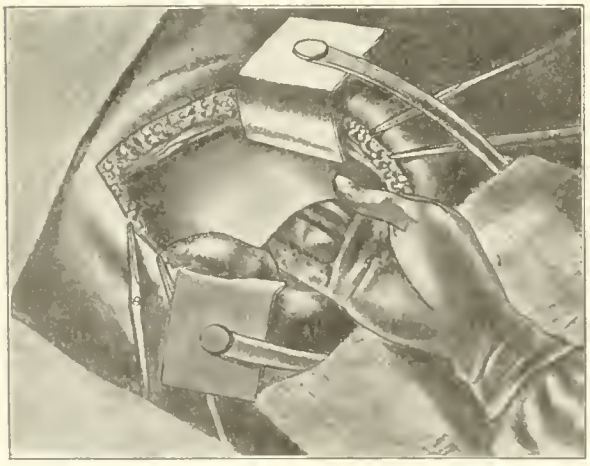

FIG. 2.—The fingers are separating the layer of dense confining exudate from the visceral pleura. The lung protrudes below. (This is, of course, diagrammatic.)

Most of our patients had been punctured before they entered the hospital and came with the established diagnosis of endothoracic suppuration. These patients, however, were *x*-rayed just the same unless their condition was so precarious that immediate relief was demanded.

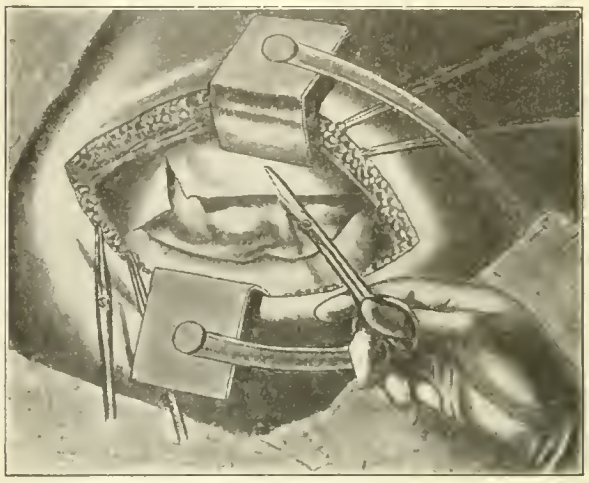

FIG. 3.—With the scissors incisions are made in the exudate to permit a freer expansion of lung.

Anesthesia.—When the empyema is secondary to pulmonary disease, as is usually the case, we believe that ether should be avoided because of the possibility of its irritating action upon the lungs. We have, therefore, employed either local, regional, or nerve-blocking anesthesia, or nitrous oxide and oxygen narcosis.

Selection and Type of Operation.—We realized that to obtain a final cure an active pneumonia, a perforating subphrenic abscess, hepatic or otherwise, or an infecting bronchiectasis, might require medical or surgical treatment more than the consequent empyema; yet a patient coming to the hospital cyanotic and gasping, the heart embarrassed by dislocation, had to be immediately relieved. His complete restoration might be a matter for later consideration. Accordingly, these cases were treated by what we have termed minor thoracotomy, though in the beginning of our work there were a few operations by the old method. (See table I.)

FIG. 4.—Case 1. (F. B.) Large right sided encapsulated empyema.

This table includes all cases in which primary operation was performed, regardless of the cause

of the empyema. March 25, 1914, to March 24, 1916.

Table I—General Table of Operations.

Minor Thoracotomy		Major Thoracotomy		Resection for Encapsulated Empyema		Resection (Old Method)		Miscellaneous		Remarks.
Total.	Died.	Total.	Died.	Total.	Died.	Total.	Died.	Total.	Died.	
24	4	26	5	4	0	5	1	4	3	Miscellaneous cases were: 2 liver abscesses; died. One large lung abscess with perforation empyema; died of hemoptysis. One old gunshot empyema; spontaneous rupture; well.

1. *Minor thoracotomy*—except for its name—is nothing new. The procedure is described as follows:

Under local anesthesia a small incision is made, preferably in the seventh or eighth interspace, in the posterior axillary line and carried through the pleura. The ribs are separated by spreading the blades of a dressing forceps or a pair of scissors and a small tube is slipped into the chest. Or, after the short skin incision, a trocar and cannula are made to enter the pleura and a drainage tube is pushed through the cannula which is then withdrawn leaving the tube in place. There are various devices to prevent pneumothorax. We have found the simplest to be a permanent syphon to keep the tube full of fluid and so arranged that the level of the liquid in the water supply bottle is lower than the patient's chest, while the tube leading from the chest has its end submerged in weak antiseptic fluid in a vessel on the floor.

Table II—Operations Compared by Ages.

	Minor Thoracotomy.		Major Thoracotomy.		Resection for Encapsulated Empyema.		Resection (Old Method).		Miscellaneous.	
	Children.	Adults.	Children.	Adults.	Children.	Adults.	Children.	Adults.	Children.	Adults.
	18	6	13	13	3	1	4	1	0	4
Died	4	0	3	2	0	0	1	0	0	3
Aged.	1½, 2, 3, 4		2, 3½, 4	35, 55			1½			25, 27, 32

Total cases	63	Total children under twelve years	38
Total deaths	13	Deaths	8
Mortality rate	20.6 per cent.	Mortality rate in children	21 per cent.
Or, omitting the two liver abscesses, 61 cases, 11 deaths.		Total adults	25
Mortality rate	18 per cent	Deaths	5
		Mortality rate in adults	20 per cent.

In favorable cases this operation is all that will be necessary. The lung expands, the discharge lessens, and recovery follows.

During the two years covered by our table we operated in 24 cases by this method with 4 deaths or 16 per cent. These deaths were due to pneumonia or general severe sepsis—often with persistent diarrhea—median suppurative otitis and metastatic abscesses, the patients being in too low a state for more thorough surgical work. Case II.)

When these minor thoracotomy patients were improved but showed no sign of prompt healing, we considered them suitable subjects for what we have termed major thoracotomy. This operation, however, was performed at the first sitting whenever the case did not look absolutely desperate.

2. *Major Intercostal Thoracotomy with Exploration and Lung Mobilization.* (The procedure has been described in an article by Lilienthal, *Ann. Surg.*, September, 1915.) Briefly, the steps of the operation are as follows: (*a*) Skin and muscle incision in the seventh or eighth interspace. Line of incision from the angle of the ribs to the anterior axillary line, more or less, and close to the upper border of the lower rib, to avoid nerves and vessels. (*b*) Pleura entered carefully to avoid possibly adherent lung. (*c*) Rib retractor inserted and the ribs separated from 4 to 6 inches or more. If still greater room is needed cut a rib or two above or below the wound at the posterior angle. (*d*) Exploration. Removal by suction or sponging, of all pus and coagula, then inspection and palpation of lung and pleura.

Adhesions to the chest wall should not be disturbed unless they separate easily. If the lung expands and fills the chest when the patient strains, and if no sign of lung abscess or fistula is present, the soft parts of the wound may be approximated with chromicized gut and the skin partly closed by suture.

Because of the division of the intercostal muscles the ribs will not at once fall together. There will be a space of an inch and a half or more (in adults) which will persist for some days. Drainage openings of suitable size anteriorly or posteriorly or both may be left, but it is not often necessary to put in tubes or gauze. Should an inoperable pulmonary suppurating lesion be encountered—bronchiectasis or lung abscess—better resect a piece of rib with the periosteum so as to permit of long-continued drainage without a tube and without the danger of valve formation and tension pneumothorax.

If the lung is bound down by tough exudate upon the pleura this should be divided by long vertical incision (Fig. 1), when the lung will usually try to force its way out of its confining membrane. Peeling this away with the fingers (Fig. 2) the lung may be further freed by incisions at right angles with the first one (Fig. 3). Hemorrhage is moderate, often absent. A slight wound of the lung tissue is not serious. Tough adhesions of the lung to the chest wall had better not be disturbed unless they are capable of being divided between ligatures. The loose flaps of membrane peeled from the lung may be cut away, but there should be no

special effort made to denude every portion of the lung's surface.

During the procedures just described secondary abscesses may be found and turned into the main cavity. Sometimes the lower lobe of the lung is

Fig. 5.—Case 1. (F. B.) Secondary antero-mesial encapsulated pyopneumothorax. Note fluid level.

adherent to the diaphragm. This adhesion should be loosened with the greatest caution for fear of entering the abdominal cavity. We have several times encountered between lung and diaphragm collections of pus which must have caused serious complications had they not been emptied.

Having mobilized the lung the wound is closed with tubeless drainage as just described.

We repeat that this mobilization and exploration through the large incision—or major thoracotomy, as we think it should be called—is not advised as a primary procedure for the desperately ill patients. It should follow minor thoracotomy, the operation for immediate relief. Doubtless, in cases without confining membranes one of the various suction apparatuses with a fixed paracentesis cannula will prove efficient. One of the best of these is that of Philips. (Demonstrated before the Surgical Section, Academy of Medicine, April 7, 1916.)

We have performed in our hospital service 26 major thoracotomies with 5 deaths, or 20 per cent.

The fatal endings may be classified as follows:

1. A. S., man, 35 (one stage), gangrenous pleurisy.

2. Bessie T., girl, 3½ (one stage), pneumonia, six weeks after operation.

3. O. W., man, 55 (two stages), sepsis (*x*-ray, suspicious of tuberculosis, but the pus showed the pneumococcus).

4. N. T., boy, 2 years (one stage), sepsis; diarrhea.

5. L. C., girl, 1 year (two stages), pneumonia; sepsis.

The operation appears to us surgically sound. It gives a far better opportunity than any other for thorough exploration and rational treatment. Pockets of pus are discovered which could not otherwise be found. In two cases subphrenic abscesses —evidently the determining cause of the empyema —were discovered, though in both instances the patients died weeks afterwards of the pylephlebitis with the liver abscess which caused the empyema. (Case 4.)

During the after treatment it is easy to explore the chest digitally when retention is suspected or, if necessary, to reopen the whole wound for more thorough visual examination.

This operation differs from that of Fowler, Delorme and Lloyd in the enormous exposure with little danger, and little hemorrhage, and, too, the deformity following multiple rib resection is, of course, absent. We avoid the great thoracoplastic operations, which seek to bring a rigid chest wall down to the collapsed lung, by mobilizing the lung and bringing it out to the normal thoraic limits. We repeat that out of all our cases, an unselected series of 63 there was not one thoracoplasty.

3. *Thoracotomy for Encapsulated Empyema.*—When the physical signs and the radiograph indicate the presence of localized intrapleural abscess, whether interlobar or not, the operation must be planned according to the situation of the disease. Often the costal pleura forms one wall of the abscess, and in these circumstances we have resected ribs directly over the pus, trying to avoid infecting the general cavity. (Case 3.) The case is then treated as an ordinary abscess. It has been found effective to remove a section of at least one rib with its periosteum so that this abscess can be treated by packing with gauze and later, if necessary, by drainage with a short tube. The removal of the periosteum with the rib prevents the rapid growth of deforming bony bridges which so frequently interfere with proper drainage. We have dealt with four of these cases and all the patients recovered.

This paper is not a plea for any one operation, but for an abandonment of routine in the treatment of empyema. Each case should be studied and its

Fig. 6.—Case 1. (F. B. Patient is well. Note cicatrix following intercostal drainage of secondary empyema.

therapy determined according to its individual requirements. We believe that the poor showing of the results in this disease is largely due to the employment of rule of thumb methods.

Case I.—*Sacculated Empyema of Thorax; Double*

Sacculation. Thoracotomy with Rib Resection; Secondary Anterior Thoracotomy. On January 19, 1916, Frank B., 24 years old, was admitted to the medical service of Mt. Sinai Hospital. His temperature at that time was 103½°, pulse 100, respiration 36.

Five years before admission he had had malaria in

Fig. 7.—Same patient as in Fig. 6. Shows main intercostal cicatrix.

South America. His present illness had begun five days before admission, with cough, fever, and bloody sputum. He passed through a rather sharp pneumonia of the right side, and on February 2 the chest was aspirated in the fourth space posteriorly in the axillary line, and thick pus was found. He was then transferred to the first surgical service for operation.

The blood count was 23,600 white cells, polys 84 per cent., lymphocytes 16 per cent., red blood cells 5,040,000. The *x*-ray showed a shadow which apparently indicated an encapsulated empyema from the right apex along the right side of the chest next to the ribs down almost to the base. (Fig. 4.)

On February 3, 1916, in nitrous oxide and oxygen anesthesia by Dr. Branower, an incision was made in the seventh interspace, the lung being supposed to be adherent at this point. The seventh rib was resected with the periosteum and clean pleural cavity invaded at the inner end of the wound. This opening was made before the evacuation of the empyema and it was closed by a suture and a gauze packing. The empyema itself was then opened through much thickened parietal pleura and a large quantity of pus escaped. On exploration the lower lobe of the lung was found soft and expansile, the remainder of the cavity lined with tough membrane. Part of this membrane was peeled away, allowing good lung expansion, and it was thought that the entire pus collection had been evacuated. Exploration showed the cavity to be cleanly marked, and on completely emptying it there was no leakage from anywhere else. Dr. Wessler of the Roentgenological department was present and stated that it was his opinion that the pus extended up to the apex. Therefore, aspiration in the axilla was practised and thick yellowish pus of a different color from that below was encountered. A section of the sixth rib was now excised at the site of the original wound and following a long aspirating needle put in as close as possible to the costal side of the chest a second large cavity was opened with dressing forceps. The entire bilocular cavity was now packed with gauze and patient sent back to bed.

On February 15 he was again *x*-rayed because of a rise in the temperature and a collection of pus anteriorly and against the mediastinum was found. There was considerable gas above the pus. (See Fig. 5.)

Under nitrous oxide and oxygen anesthesia, a small anterior fourth interspace incision was made, and gas and pus evacuated; tube drainage. Under postural treatment this rapidly closed and the patient was discharged well on March 6, 1916. The illustrations (Figs. 6 and 7) show the sites of the cicatrices.

This case illustrates beautifully the value of the *x*-ray in accurate diagnosis, pointing the way to intelligent and prompt surgery.

Case II.—*Empyema of Thorax, General Sepsis, Double Otitis Media; Death.*—On February 6, 1916, Celia M., four years old, was admitted to Mt. Sinai Hospital. Her temperature was 103.4°, pulse 144, and respiration 40. For two days she was a patient in one of the medical wards, and was transferred for operation.

When the child was fifteen months old she had some indefinite intestinal trouble, with loss of weight and weakness, which continued for three months.

The illness for which she entered the hospital had begun eighteen days before admission, with cough, high fever, and dyspnea. When transferred to the surgical service she was acutely ill and extremely septic in appearance. There was herpes prolabialis, great dyspnea, both ear drums were perforated, and the ears discharging. The left lung was apparently normal. The right chest was full of fluid; the heart displaced; Grocco's sign present. The day before her transfer she had been aspirated and one cubic centimeter of purulent fluid had been withdrawn. The blood showed 11,500 white blood cells, with 86 per cent. polys and 14 per cent. lymphocytes.

On February 8, 1916, in local anesthesia with alypin, a short intercostal incision was made in the eighth interspace behind the posterior axillary line, and a large quantity of pus was evacuated. The pus was later shown to be pneumococcal. The chest was drained by means of a small tube and permanent suction was arranged with the water syphon. The patient continued extremely septic, lying in a semiconscious state and being fed with difficulty. With slight variation the progress of the case continued for about a week, when there developed ecchymoses of large size upon the face. A blood culture resulted in the diagnosis of pneumococcemia.

In this desperate condition a transfusion of 80 c.c. of blood from the patient's mother was made by the sodium citrate method, and this was repeated twice within the next two days. Needless to say the necessary tests were previously carried out. After each transfusion there was evanescent improvement, but the child died in coma ten days after the operation.

Fig. 8.—Case 3. (S. M.) Large axillary encapsulated empyema. Cured by resecting ribs in axillary region.

The wound showed no sign of gangrene and the discharge had considerably diminished.

Carefully reviewing this case we believe that nothing at present known to science could have saved the patient. Her death was due, not to the

empyema nor to the operation, but to the effect of the pneumococcal bacteremia.

CASE III.—*Encapsulated Empyema of Thorax, Rib Resection, and Drainage.*—Samuel M., 24 years old, was admitted to the medical service of Mt. Sinai Hospital on December 10, 1915, and was transferred to the surgical service on January 13, 1916.

Eight years before admission he had had pneumonia, and three years before tonsillitis. His present illness had begun on December 8, two days before admission, with pain in the left chest, vomiting, chills, fever, and headache. Then with an increase of all the symptoms there came cough, with scanty expectoration. Finally, dyspnea and precordial pain.

Physical examination showed a very sick patient, tongue dry and coated. In the lungs anteriorly from the apex to second rib on the right side there was exaggerated inspiration with a few râles; no dullness; posteriorly from angle of scapula to base dullness with bronchial respiration and voice over scattered areas. The left side from the midscapular region to the base showed dullness, increased tactile, and vocal

FIG. 9.—Compare with Fig. 7. This patient has had several thoracoplastic rib resections. Note deformity and rigid scapula.

fremitus, bronchophony, numerous crepitant râles. Urine not abnormal. The blood count was 27,000 white blood cells, 87 per cent. polys, 13 per cent lymphocytes. The *x*-ray showed an oval shadow of large size in the upper part of the left chest with an opacity below connected with upper opacity by what might be called an isthmus. (Fig. 8.)

This patient had been aspirated a number of times by the medical men and finally, on January 4, pus was obtained in the fifth space in the midaxillary line.

On January 13, 1916, as soon as possible after the transfer to the surgical service, the patient was operated upon. In nitrous oxide and oxygen anesthesia, administered by Dr. Branower, an incision perpendicular to the line of the ribs was made in the left axillary region and portions of the fourth and fifth ribs were removed with the periosteum. At once a large collection of pus was encountered and the anatomical conditions suggested by the *x*-ray were easily made out. There was a strong tendency to expansion of the lung and the wound was packed with gauze and permitted to drain without a tube. The patient made an uneventful recovery and was discharged well in twenty-five days.

CASE IV.—*Pylephlebitis Following Appendicectomy; Secondary Empyema of Thorax; Death.*—Abraham E., 27 years old, had been operated upon for acute gangrenous appendicitis, at the New York Post Graduate Hospital, seventeen weeks before I saw him. Later the diagnosis of pylephlebitis was made and the gall bladder was opened at the same hospital.

On December 29, 1915, he entered one of the medical services at Mt. Sinai Hospital in a wretched condition, and eleven days later he was transferred to the first surgical service for operation, pus having been found on apirating the left upper chest. There was edema of the extremities.

The urine contained albumin and red blood cells, but no sugar. The blood showed 6,100 white cells, with 87 per cent polys and 13 per cent lymphocytes. Before the aspiration at which pus was obtained there had been other aspirations when clear green-yellow fluid with 89 per cent. of polymorphonuclears and 11 per cent. lymphocytes had been withdrawn. No growth on culture. *X*-ray examination showed two distinct fluid levels in the left chest, one below, the other above.

The empyema being apparently the most urgent condition, he was operated upon on January 10, in nitrous oxide and oxygen anesthesia. A long incision was made in the eighth interspace and the eighth rib was widely resected with its periosteum. The rib spreader was put in. An enormous amount of gas under tension and exceedingly foul pus was evacuated. It was later found that this pus contained *Bacillus proteus*. The lower lobe of the lung was adherent to the diaphragm and there were numerous other adhesions in the chest, some of which were peeled loose, and one which divided the chest apparently into two main cavities was divided with scissors. Dense adhesions in the upper chest were not interfered with. The lung was covered with a greenish exudate, but on peeling some of it away from the lower lobe there was no expansion. With a very guarded prognosis this operation was concluded by closing part of the wound with suture and leaving the rest open for drainage.

By January 24 there was great abdominal distention from ascites, and under local anesthesia a tiny transverse epigastric incision was made in the hope of coming down upon an hepatic abscess. Repeated puncture through this incision revealed no pus, although the liver was much enlarged and the abdomen contained a quantity of seropurulent exudate. The prognosis was now bad.

A few days later paracentesis in the left iliac region was performed and the opening permitted to drain for ten days. This gave considerable relief, but the fluid reaccumulated and the patient's condition became desperate. Finally, intestinal obstruction developed and the patient refused operation until fecal vomiting appeared and he was almost moribund. On February 26 laparotomy under nitrous oxide and oxygen disclosed a tough band of adhesions binding the ileum to the anterior abdominal wall. The obstruction was relieved, but on account of the cirrhotic condition of the liver even the slightest adhesion between the intestine and the abdominal wall bled furiously. The patient survived for twenty-four hours, vomiting constantly, then died. A small piece of the liver was secured and examined by Dr. Mandlebaum, who reported a probable healed pylephlebitis, from the history and from the fact that there was a recent cellular cirrhosis.

The case is reported here very briefly because of the complication of thoracic empyema. The death of this patient was not due to his empyema even remotely.

There was another case which is included in our table very similar to this one, in which a direct perforation occurred between a liver abscess and the right lower pulmonary lobe. At operation a serous effusion was found in the chest and on peeling away the lung from the diaphragm an abscess was evacuated. Later the diaphragm was opened and the main abscess drained. This patient also died of his liver sepsis.

THE CAUSE, TREATMENT, AND PREVENTION OF HAY-FEVER.

By W. SCHEPPEGRELL, A.M., M.D.,

NEW ORLEANS.

PRESIDENT, AMERICAN HAY-FEVER-PREVENTION ASSOCIATION; EX-PRESIDENT, AMERICAN ACADEMY OF OPHTHALMOLOGY AND OTO-LARYNGOLOGY, ETC.

UNTIL recently, hay-fever was considered a disease of varied and doubtful origin, but whose reappearance was as certain as the proverbial tax-collector. A more exact knowledge of the etiology of this disease, however, has shown not only that it is not inevitable, but, in view of the simplicity of its prevention, is a disease whose contained existence would be a reflection on preventive medicine.

The development of pollinosis at the exact time of the blooming of certain plants, and its disappearance with these flowers, eventually led to the conclusion that a relationship existed between hay-fever and the blooming of these plants. This was corroborated by the fact that susceptible persons develop a paroxysm by simply approaching such plants at a time when their pollen is being dispersed by the wind. It was also found that this pollen, applied to the nostrils of susceptible subjects, could produce a hay-fever reaction at any season of the year.

The class of plants whose pollen may cause hay-fever are wind-pollinated, that is, the process of fertilization is effected by the pollen being borne by the wind, instead of this being done by contact or by insects. This explains the presence of such pollen in the air. In some cases the pollen is present in

FIG. 1.—Common ragweed (*Ambrosia artemisiafolia*). Responsible, with the giant ragweed, for 85 per cent of fall hay-fever. More common in the Middle and Northern States.

enormous quantities, as for instance in the ragweeds, in which it has been estimated that only one in a hundred million pollen is actually used in fertilizing the pistillate flower.

The plants that are responsible for hay-fever are practically all common weeds, such as the ragweeds, cockle bur, yellow dock, etc., which are also a source of expense and labor to the farmer. Their characteristics are as follows: They are wind-pollinated, without attractive color or fragrance, very

FIG. 2.—Giant ragweed (*Ambrosia trifida*), whose pollen is one of the chief causes of hay-fever. Grows in moist lands. Very abundant on the Gulf Coast. (From "Hay-Fever and Its Prevention," by W. Scheppegrell, A.M., M.D. Report of United States Department of Public Health, June 30, 1916.)

numerous, and with abundant pollen. The lack of color or scent is due to the fact that these plants are wind-pollinated, the qualities mentioned being intended to attract insects for fertilization.

The most common weeds that cause hay-fever are the rag-weeds (*Ambrosia artemisiæfolia* and *trifida*, Figs. 1 and 2), which are the causes of most cases of fall hay-fever. The marsh elder (*Iva ciliata*, Fig. 3) is also a cause of fall hay-fever and frequently prolongs the attack. The early cases are due to the yellow dock (*Rumex crispus*, Fig. 4), and the mid-summer cases to the careless weed (*Amaranthus spinosus*), cockle-bur (*Xanthium canadense*, Fig. 5) and other wind-pollinated weeds. In early summer, many cases are due to the various grasses (Fig. 6), all of which are wind-pollinated.

The reaction of pollinosis is divided into the direct and indirect stage. The former is influenced by the physical conformation of the pollen. In plants, in which the pollen is covered with spiculæ, such as the Ambrosias, Partheniums, Dracopis, etc., the direct reaction may develop immediately and is usually prolonged. In those in which the pollens are smooth, such as the Rumex, Amaranthus, grasses, etc., the reaction is deferred several minutes and is milder in character.

The indirect reaction of pollinosis is partly due to the effects of the primary irritation and partly to the absorption of the protein contents of the pollen, and the toxin formed by the proteolytic

action of the cells. The immunity of the patient depends upon his resistance to the initial irritation and the completeness with which the liberated toxins are neutralized. The character of this process establishes the degree of susceptibility of the

Fig. 3.—Marsh elder (*Iva ciliata*), a cause of fall hay-fever.

patient and forms an important factor in what is called "predisposition." This is probably also affected to some extent by certain general conditions but the influence of these has not been clearly established.

Immunity and predisposition in pollinosis are relative terms. The person who is immune and the one which is affected may both breathe the same pollen-infected air, the former without apparent discomfort and the latter developing an attack. In each case, the pollen enters the nasal cavities, but in the immune, the clinical symptoms are not presented.

This result is due to the fact that all cells possess to some extent a proteolytic power which acts as a defense against the invasion of foreign proteins, provided certain limits are not exceeded. In addition to this, the entrance of foreign proteins by parenteral channels results in the development of antibodies, which are ferments which also protect the host within certain limits. The extent to which these processes neutralize the absorbed toxins, and the degree to which he can resist the initial irritation, establishes the degree of immunity of the patient.

Local conditions, such as abnormalities of the nasal passages, also act as a predisposing cause, but much less so than is generally supposed. Operations to correct such defects have given satisfactory results as regards hay-fever in less than 25 per cent of the cases, and are not to be recommended unless also indicated for other reasons.

The increased susceptibility of hay-fever after an initial attack, is due to the anaphylactic condition produced by the absorption of the pollen protein by parenteral channels. The antibodies resulting from this reaction are probably of the anaphylactic type, and this explains the reduced resistance to further infection.

Anti-anaphylaxis, eventually resulting in a reactive condition of immunity, also develops in pollinosis, but is usually delayed for quite a long period, and is indicated by gradual decrease of the paroxysms. This should not be confused with the disappearance of the attacks due to diminution of the supply of pollen resulting from a change of residence or the eradication of the pollinating weeds.

The effects of hay-fever are due not only to the absorbed pollen proteins but also to the action of microorganisms resulting from the lowered resistance of the nasal mucous membrance, and from the inflammatory reactions associated with these processes. In the treatment, these various conditions should be considered.

The important factor in the treatment is the removal of the exciting cause. In many cases, the pollinating weeds are in the neighborhood of the patient's residence, and the cutting of these will frequently give marked relief. My first prescription to such patients is "Have the weeds and grass in your neighborhood cut and keep away from other weeds." The result of this advice depends upon the extent to which the pollinating weeds and grasses can be cut or destroyed, but the results compare favorably with the published reports of therapeutic methods.

A method which has given relief in almost every case, is the removal of the patient during the hay-fever period from the infected locality. This does not necessitate an expensive trip to the mountains or seaside, which frequently fails to give relief on

Fig. 4.—Yellow dock (*Rumex crispus*). A cause of spring hay-fever.

account of the presence of hay-fever pollens in the air at these places. A temporary visit to a more central part of the city will be sufficient, provided the areas with pollinating weeds or grasses are at a sufficient distance ($\frac{1}{2}$ mile or more). The new

locality should, however, be carefully inspected, as a small lot with high weeds in the same square may be more irritating than a whole acre of weeds at a greater distance.

For several years attempts have been made to increase the resistance of the patient to pollen by the injection of the pollen extracts. In all the early attempts, mixed pollens were used without regard to the special susceptibility of the patient, which is probably one of the causes of their failure. In such cases, only the pollen should be used to which the patient reacts, as evidenced by the nasal, conjunctival, or skin reaction. The injection of the wrong extract may cause the patient to become sensitive to the pollen from which the extract is prepared.

The pollen extract is prepared by dissolving one centigram of the specified pollen in ten c.c. of 5 per cent. salt solution to which 10 per cent. alcohol has been added and which is preserved in an aseptic condition. When used, this should be diluted to about 5 per cent., the strength to be determined by the conjunctival reaction, this being indicated by a hyperemia produced by the extract. The subcutaneous injection of the extract should be repeated at intervals of three to five days. The object of the injection is to increase the patient's resistance to the pollen toxin (anti-anaphylaxis) so that the inhaled pollen protein will no longer produce an attack.

Instead of the conjunctival reaction, the skin reaction is frequently used. This is effected by making a number of light scratches on the skin and rubbing in a drop of the pollen extract to be tested. A positive reaction is indicated by reddening and edema of the area surrounding the abraded surface and accompanied by itching.

In cases in which the pollen therapy does not give satisfactory results, autogenous vaccines may also be used. These are prepared from the bacteria found in the nasal secretion of the patient. Both of these methods have given fairly satisfactory results, whose permanency, however, still remains to be established.

Relief has also been reported from the use of calcium chloride, which already has been successfully used in asthma, the dose being 3 grams daily. It is supposed to act as a sedative to the nervous system.

Mercury has also been used in hay-fever, and Barton L. Wright of the United States Navy reports several successful cases. He prefers the succinimide of mercury, 1/5 gr. in distilled water, this being injected deeply into the gluteal muscles. He believes that the effects are due to the fact that patients after a mercuric treatment have a peculiar power of resistance to infection of every kind.

In regard to treatment, however, it must be admitted that thus far none except the elimination of the pollinating weeds has given very satisfactory results. The above methods are described as the most promising thus far. Further investigations along these lines it is hoped will eventually give sufficient data to indicate the most advisable method of treating this disease.

As hay-fever has been shown to be a distinctly preventible disease, it is clearly our duty to use every effort to eradicate the cause. The investigations which we have conducted for several years indicate that the large majority of the plants whose pollen give rise to hay-fever are worthless weeds which are alike an expense to the farmer and a menace to health.

In a work of such an extensive character, however, as the eradication of hay-fever weeds, we must have general co-operation in order to be successful. It is therefore necessary to educate the public in the relationship of such weeds to hay-fever and the relief that sufferers from this disease are entitled to by removing the cause. Health is one of man's most important assets, and every one has a right to demand that this does not suffer on account of the neglect of his neighbor. If the hay-fever weeds are allowed to infest his neighbor's premises or vacant lots and infect the air he breathes with noxious pollen, he is evidently entitled to relief.

In the medical profession, the relationship of pollen to hay-fever has been so firmly established that it is now technically referred to as "pollinosis." In the recent meeting of the Louisiana State Medical Society, in which I spoke of the etiology of hay-fever, there was not a dissenting opinion expressed regarding the relationship of these pollens to hay-fever.

FIG. 5.—Cockle bur (*Xanthium canadense*). A great nuisance to the farmer and a cause of hay-fever.

An important item in the eradication of hay-fever weeds is the distance at which pollen may produce an attack of hay-fever. It has been shown by means of glass slides exposed to the wind that some pollens may travel a great distance, even several miles. We have found, however, that pollen scatters rapidly as it is carried by the wind from the parent weed, the decrease being estimated to be inversely as the square of the distance. On this account, pollen is not often a source of hay-fever at a distance of over a half mile, and even a much shorter distance is often sufficient to give relief. According to the above rule, a patient at 1000 feet, or about three ordinary city blocks, would inhale only 1/100 part of the pollen to which he would be exposed at 100 feet.

Immunity to hay-fever does not mean that the patient is not inhaling pollen, but that the amount is not greater than he can neutralize. In an atmosphere in which there is an abundance of pollen, it is evident that all persons breathing this air must inhale about an equal number, but only those suffer in whom the amount of pollen inhaled is in excess of their neutralizing power. There are probably few who cannot inhale a certain number of pollen grains without disturbance, hence the importance of keeping this number as low as possible.

As an evidence of the importance of eliminating the pollen in the immediate vicinity of the patient, I have observed great relief to patients when the hay-fever weeds in lots adjoining their residences were cut down, although considerable pollen was still in the air from weeds at a greater distance.

The increased susceptibility of a hay-fever patient after an incipient attack has already been referred to. We have had patients living at a distance of a quarter of a mile from a large area of hay-fever weeds, who were entirely free for weeks until their susceptibility was increased by an attack from close proximity to these weeds. The amount of pollen at a distance which had not before been a source of irritation was now sufficient to continue the attacks.

FIG. 6.—Johnson grass (*Sorghum halapense*). Practically all grasses are wind-pollinated and may cause hay-fever. (From "Southern Grasses," United States Department of Agriculture.)

In order to be effective, the efforts against hay-fever weeds should be reinforced by proper legislation. There will always be persons who respect their neighbors' rights, in health as well as in other matters, only when compelled by the majesty of the law. When education has reached a sufficient stage, therefore, suitable laws should be enacted to obtain permanent results against hay-fever.

In New Orleans where success against hay-fever is already quite apparent, the education of the public in the relationship of certain weeds to hay-fever was carried out by means of articles in the medical and lay press and in lectures before various societies. As a result of this, when an effective anti-hay-fever-weed law was submitted by the American Hay-Fever-Prevention Association to the city council it was passed without a dissenting vote. It is now being enforced, and the results in the reduction of the number of hay-fever cases thus far (July 1) has surpassed all anticipations.

It is important in enacting such an ordinance that the provisions should not be too drastic or it will be difficult to enforce. The height of grass and weeds should be limited to one foot on lots, sidewalks, and roads operating through a public franchise. On the other hand, no preliminary notification should be allowed, as this greatly increases the expense of inspection and reporting, and lowers the efficiency of the ordinance.

As the relation of weeds to hay-fever becomes more generally recognized, adequate anti-weed laws will be introduced in all the towns and cities. Their proper observance will give results in hay-fever that will fully justify the expense of their enforcement.

844 AUDUBON BUILDING.

HAIR-MATRIX CARCINOMA.

BY FRANK WARNER, M.D., F.A.C.S.,
COLUMBUS, OHIO.

BASAL-CELLED, or hair-matrix, carcinomata occur, with few exceptions, on the head, face, or upper lip. They occasionally occur on the lower lip, the body, or the extremities.

In a recent study[1] of 206 cases of carcinomata occurring in various parts of the body, thirteen were found to be of the hair-matrix type; eleven being on the upper lip or above, one over the scapula, and one on the leg. Two of the cases were epidermoid of the cheek.

Whenever a malignant tumor develops in this upper face and head region, it will usually be found to be a hair-matrix carcinoma.

Hair-matrix carcinoma, as a type of rodent ulcer, has long been known to infiltrate broadly and slowly, but not deeply. The general understanding of this proposition has proved of great advantage to the surgeon, and in turn, to the patient. Where possible, the surgeon removes the growth with an incision fairly clear of the infiltrating edge, which can usually be determined by a rather abrupt margin, of different color from the balance of the growth, being pearly in appearance.

This cancer is the least malignant of the carcinomata. It displays little tendency to produce metastases, although these occasionally occur. For all it grows slowly, and is so feebly malignant as compared with many of the other varieties of cancer, as to make its complete removal easy. An operation will give the patient freedom from mutilation and recurrence in proportion to the thoroughness and promptness with which it is undertaken and done after its inception. Once thoroughly removed, it never recurs.

The histological picture of a hair-matrix carcinoma is quite characteristic in most cases. At times, however, it comes to resemble a sarcoma, when the usual cuboidal cells, of which it is composed, assume a spindle shape.

Mallory[2] has pointed the way to its differentation by calling attention to the fibrils which will be

found on careful examination, taking the characteristics of the cells which line the hair-matrix. Not alone the fibrils tend to differentiate the growth from sarcoma, but their tendency to arrange themselves in tubules, like the hair-matrix from which they are derived.

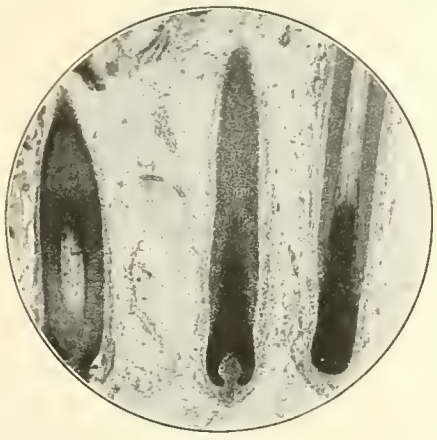

Fig. 1.—Normal hair follicles.

Adami,[3] in speaking of Krompecher's work, says that he has called these basal-celled cancers, and has "established, it would seem, beyond any doubt, that cells of epidermal, epiblastic origin can give rise to tumors indistinguishable from connective-tissue sarcomas in histological structure." Again: "We deal with an epithelioma of the most aberrent and anaplastic type, which, nevertheless, for long months, and it may be, years, continues to grow and locally infiltrate and destroy the surrounding tissue."

Ewing[4] has made some interesting observations on the resemblance of certain spindle-cell carcinomata to sarcomata. He says: "Epithelial tumors may from their inception appear like spindle-cell sarcoma, as in the spindle-cell, basal-cell carcinomas of Krompecher, in spindle-cell carcinoma of the thyroid, and in melanoma. It is becoming more and more apparent that many so-called sarcomas of the organs are in reality spindle-cell carcinomas. . . . Spindle tumor cells are so common in carcinoma that their occurrence in any carcinoma is very strong presumptive evidence that they are altered epithelium."

The disposition to keratinization into epithelial pearls in basal-celled carcinomas is nowhere nearly so frequent as it is in the epidermoid variety of tumors, although Mallory speaks of their occasional appearance in minute forms.

A rodent ulcer appears as a warty growth, and indeed is frequently mistaken for a wart, which may remain for a considerable time without ulcerating; some authors say for several years, but this seems rather improbable. Rather, it would appear that the simple warty excrescence has changed its character to a malignant type of epithelial penetration and overgrowth. As has been emphasized, hair-matrix carcinomata spread very slowly and superficially.

Morrow[5] pointed out long ago a prominent distinguishing feature of rodent ulcer in contrast with an epithelioma, when he said: "The amount of infiltration or new deposit about the base and edges of a rodent ulcer is much less than in the usual variety of skin cancer, while ulceration is more marked." These are valuable points in making a differential diagnosis.

The location of the ulceration is always suggestive, in a diagnostic way, for the majority of these ulcerations occur about the sides of the nose and the eyelids, or on the head or face above the lower lip.

Again, the age of the patient is helpful in making a rightful interpretation of the character of the ulcer, or of the warty growth before it has become broken down into an ulcerating surface. It is preeminently a disease of the advanced cancer age, or of middle life.

Until recently many writers have confused hair-matrix carcinomata and epitheliomata, the one with the other. But their whole history of development and subsequent behavior are quite different. Then when a histological study of the two is made, there is no longer doubt remaining as to their true character.

In contrast to many varieties of cancer which have arisen after a prolonged period of a so-called precancerous state, hair-matrix carcinoma is quite as apt to develop on a part which has apparently been free from all forms of irritation.

Some authors have attempted to explain the development of cancer upon anatomical grounds. Theilhaber[6] thought that nutritional changes, due to endarteritis and an acellular connective tissue that are frequent accompaniments of old age, are responsible for their initiation. But the writer has shown that in a study of 206 cases of carcinoma, obstructive vascular changes occurred in only 105 cases, a little over one-half. So, the other half of the cases could not have depended upon this cause of the cancer. Likewise, the fibrotic changes were present in only 118 cases, or 57 per cent.

These anatomical changes are hardly constant enough to be regarded as offering sufficient causative agency for the initiation of malignant growths.

Internal causes of cancer, associated with external irritative ones, known as precancerous conditions, are more likely to result in the development of malignant growths than where the one cause operates alone. Perverted chemical and biological activities of the epithelial cells seem to be sufficient cause for the development of cancer, but just what these changes are, or what induces them, remains to be established. Aside from the influence that heredity plays, and the exciting causes of the well-known precancerous conditions, the etiology of carcinoma is still in the dark.

Fig. 2.—The tumor from the nose, showing tendency of epithelial cells to form into tubules.

But whatever are the causes that start epithelial malignancy, the disease is local at the outset, and all that is needed to effect a cure in any one case is to operate early enough to find the condition in its very incipiency.

Then, and only then, can the surgeon hope to make his operations universally successful. This is less true of hair-matrix carcinoma than the others, because there is slight tendency to produce metastases, or to infiltrate deeply; yet, even here,

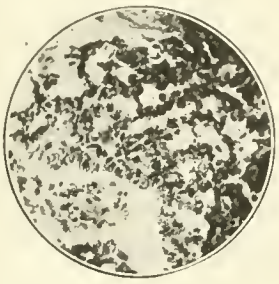

Fig. 3.—Higher magnification of Fig. 2, showing the tendency to the formation of tubules.

this form of cancer cannot always be attacked with assurance of success when it has been in existence for a long time, for infiltrations may have occurred that are impossible to reach. Hair-matrix carcinomata are, of course, on the surface of the body, where they can be seen in their earliest development. If attacked as soon as observed, doubtlessly 100 per cent. of recoveries would result.

As illustrative of the results to be attained by early operations on hair-matrix carcinoma, the following two cases are appended:

Case I.—Mr. J. A. C., age 53, came to me Nov. 20, 1909, for a slight lump on his forehead, over the left eye. This had been in existence for six months. It was small and only slightly elevated. The edges of the elevation were higher than its center, and the color was lighter, slightly pearly in character. There was no ulceration of the surface, but the whole appearance of the disturbance was that of an early rodent ulcer, or hair-matrix carcinoma. No pain was associated with the growth. On November 24, 1909, I removed the tumor with a rather wide incision, quite clear of the growth. The wound healed promptly, and there has been no reappearance up to the present time, being nearly seven years since the operation. The tumor was a hair-matrix carcinoma.

Case II.—D. I., age 43, male, consulted me with reference to a small lump on the right side of his nose. It was about the size of a pea, with pearly edges, but no ulceration. The tumor had only been observed a few weeks previously. No pain had been experienced in the growth. A circumstance that made one feel that the tumor was about to ulcerate was the fact that soon after its first appearance, or at least, since its presence had been observed, bleeding occurred from a small vein traversing the growth. This healed at once, so that no ulceration was observable at the time of the examination.

This growth was removed on October 22, 1914, by an incision which well cleared the outermost edges of the tumor, and the actual cautery, a platinum point heated by electricity, was applied to both the base and the edges of the freshly made wound. This was done as a precautionary measure to destroy any infiltrating can-

Fig. 4.—Showing change to cells of a spindle shape

cer cells that possibly might have escaped the knife. There has been no evidence of its recurrence. The histological structure of the growth proved it to be a hair-matrix carcinoma.

The results in both of these cases emphasizes the fact that we may reasonably hope for a complete freedom from recurrence in hair-matrix carcinoma when the operations are done early in their progress, for it is well known that at this time these new growths do not tend to infiltrate deeply, nor to

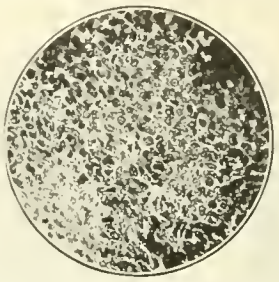

Fig. 5.—The tumor cells are packed closely together and appear only as small round cells.

metastasize, nor to show a high degree of malignancy.

Finally, when we come to reflect how absolutely curable this disease is in its early inception, and how easy it is to make a probable diagnosis at this time, and what a slight operation is required to effect this much desired result, there seems little occasion to delay these trifling operations that promise so much. As has been shown in this paper, there is not alone this more extensive infiltration to encounter in delayed operations, but there is the constant danger present of an epithelioma engrafting itself on the edges of the ulcerating growth. Then a tumor of a higher grade of malignancy is there to deal with. By this time, metastases may have occurred in neighboring glands, or elsewhere, and infiltration of epithelial cells into depths that are not reached by an operation.

To obtain better results in our operations for cancer of all forms, earlier diagnoses must be made, and earlier opportunities given the surgeon to do these operations.

THE ACTION OF GAMMA-RAYS OF RADIUM ON DEEP-SEATED INOPERABLE CANCERS OF THE PELVIS.

By HENRY SCHMITZ, A.M., M.D., F.A.C.S.,

CHICAGO.

Radium therapy of malignant tumors in any part of the body demands the discussion of the following points: (1) The technique of the application of radium, (2) the evidence of the histological changes caused in the tumor tissue, and (3) the clinical results; it also must include a discourse on all accessory means which will assist the action of radium, such as (4) the application of the massive Roentgen rays, and (5) the use of surgical procedures to facilitate or aid the intensity of the gamma-rays of radium.

The Technique of Radium Applications.—The technique of the application of radium must consider (1) the amount of radium element used,

(2) the method of screening, (3) the extent of the time of exposure of the rays to the tumor, and (4) the distance maintained between the radium and the tumor mass. The quantity of radium necessary to destroy growths, that reach two or three

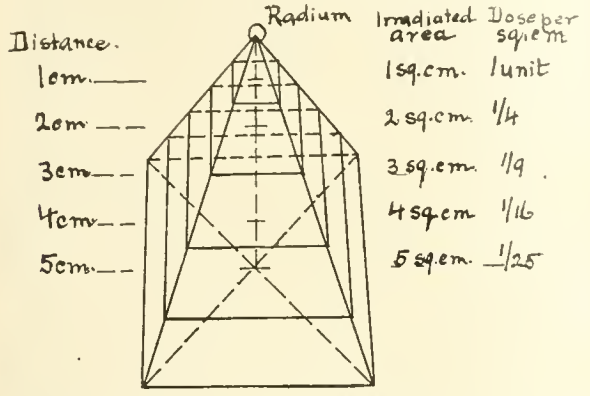

Fig. 1.—Law of Radiation.

centimeters into the uterine, rectal, vesical and pelvic cellular tissues, should be at least fifty milligrams of radium element. If the capsule cannot be brought into direct contact with the tumor, then a sufficient intensity of the rays must be obtained by the use of larger amounts of radium element.

To determine the dose of gamma-rays necessary to destroy carcinoma tissue we make use of the law of radiation and experiments carried on in the living human body. The intensity of the action of rays varies inversely as the square of the distance from the source of radiation. The irradiated area at a distance of one centimeter may be considered as one square centimeter and the dose of rays for this area as one unit. At two centimeters, the irradiated area is four square centimeters and the dose one-fourth of a unit, and at three centimeters the irradiated area is nine square centimeters and the intensity of the rays is one-ninth of a unit. (See figures 1 and 2). If for instance, fifty milligrams of radium element destroy a tumor mass within a distance of one centimeter from the radioactive substance in twelve hours, then the same amount will bring about the same result within a distance of two centimeters in forty-eight hours, and within a distance of three centimeters in 9 x 12 = one hundred and eight hours. Or if fifty milligrams radium element destroy a tumor mass within one centimeter distance, in twelve hours, then two hundred milligrams radium element will do so in twelve hours within two centimeters distance and four hundred and fifty milligrams radium element in twelve hours within a distance of three centimeters. However, it has been found that more than one hundred milligrams radium element should not be used at a given point, and if a larger amount be used, it is better to distribute each hundred milligrams to various parts of the tumor, as is done in the method of cross-firing. The reasons are that large amounts of radium cannot be properly concentrated into a sufficiently small area of space, so that the law of radiation may be correctly applied.

The experiments in the human body were carried out in recurrent breast cancers, characterized by the formation of multiple nodules. A nodule was removed under local anesthesia and subjected to a microscopic examination to determine its pathological nature. Then the gamma-rays of fifty milligrams radium element were applied for four hours to a given nodule, for six hours to another nodule, for eight hours to a third, for ten hours to a fourth, for twelve hours to a fifth, and so forth. After ten to fourteen days, *i.e.* when the latency of the action of the gamma-rays reaches its height, the nodules were removed. We noted particularly the distance of the growths from the skin surface. The removed tissues were subjected to microscopic examinations. In this manner we repeatedly demonstrated the fact that the gamma-rays of fifty milligrams radium element destroyed carcinoma tissue within a distance of one centimeter from the skin surface after a continued application of twelve hours, *i.e.* six hundred milligram hours or milligramage.

The receptivity or sensitization of carcinoma tissue toward the gamma-rays varies, depending upon the age of the individual and a corresponding difference in the vascularity and nucleization of the tissues as well as on the variety of species of the cells composing the tumor. H. Dominici and Theilhaber have made extensive investigations along these two points. For practical reasons the above dosage of milligram hours, when fifty milligrams of radium element are used, may be considered as lethal.

Dose per sq. cm.				
1 unit	¼ unit	1/9 unit	1/16 unit	1/25 unit

If we determine by a careful examination the extent of the tumor mass and apply the radium according to facts given, we will be able to estimate for each case, the amount of gamma-rays necessary to bring about a clinical cure.

The schedule of a course of radium applications, based on these facts, is as follows: The duration of a course of treatment varies from twelve to one hundred and eight hours, when fifty milligrams of radium element are employed and this depends on the extent of invasion of the cancer into the tissues. The course is divided into séances of twelve to twenty-four hours, the interval between the sittings being from twelve to thirty-six hours. We endeavor invariably to give the total estimated within one week.

If one hundred milligrams of radium element are used, then the duration of the treatment is correspondingly reduced. Should it be impossible to apply the radium directly to the tumor mass, longer exposures or large amounts must be used to correct the reduction of the intensity of the rays caused by the increase in distance. The law of radiation must be applied in consideration of these facts.

The method of screening or filtering is simple as gamma-rays only must be used in deep-seated cancers. The alpha-rays of radium are arrested by the glass capsule, which contains the radium salt. The beta-rays are absorbed by 1.2 mm. brass, silver, or lead. The secondary or Sagnac rays, that form in the metal screens by the arrested beta-rays, are absorbed by a pure rubber tube free from any metal and of 2 mm. thickness. They are also arrested within a space of 7 mm. and therefore distance filtering may obviate the need of a rubber filter.

Cross-firing should be employed whenever possible. If a carcinoma is found in the anterior rectal wall a radium capsule should be inserted in the rectum and another in a corresponding position within the vagina; if in the posterior rectal wall in the rectum and on the anal fold, if in the posterior vesical wall in the bladder and vagina; if in the anterior vesical wall into the bladder and on the suprapubic region, if in the cervical canal, the latter and the vaginal fornices, and so forth.

Special radium carriers are required for rectal and vesical applications. For the former I use a cup with a perforation in the center. It is held in place by two rubber bands fastened to a belt around the abdomen. The radium carrier is attached to a brass rod which is surrounded by rubber tubing. The latter arrests also the secondary rays. The length of the rubber tubing is determined by the distance of the growth from the cup. The brass rod passes through while the rubber tube rests on it. The carrier by this arrangement remains movable and therefore becomes automatically adjusted to any position the patient might assume. In vesical cancers I place the radium capsule in a urethral catheter. Two fenestræ are made in the catheter beneath the radium capsule. As vesical cancers are usually located in the trigone the position of the catheter within the bladder is indicated by the escape of urine through the tube. The latter is then secured in place by adhesive plaster. A rubber tube attached to the catheter directs the urine into a bottle. Continuous drainage is thus secured, making long-continued applications of radium within the bladder possible.

After the first course of radium treatment the patient is requested to return weekly for reexamination. The latent action of radium reaches its height within twenty-one days. Should the patient at this time not exhibit a marked improvement in the local condition, indicated by a decrease in size of the tumor, another course like the first one is given. If the patient shows a marked improvement, then the second séance is postponed for another three weeks. Further applications are thereafter given when indicated by a persistence or a reappearance of the tumor.

Strictest asepsis must be observed in the application of radium. Instruments and applicators must be rendered sterile by boiling. The field of operation must be prepared as for any operation. The surgeon also must adopt the same procedures as he would for the performance of any operation.

Healthy tissue must be protected from the rays wherever practicable. Lead sheeting 0.5 mm. thick is used for this purpose. It is cut and shaped to correspond to the dimensions and form of the area to be protected from the action of the rays. The Sagnac rays are arrested by surrounding the lead sheeting with heavy soft rubber sheeting. The latter also serves as a cushion to prevent undue pressure and thereby injury to the soft tissues.

The Use of Massive Roentgen Rays in Connection with Radium Treatment.—We cannot determine by bimanual examination whether the regional lymph-nodes are or are not metastatically invaded by the carcinoma. Therefore, we apply massive *x*-rays to the glands through the anterior abdominal wall by the massive multiple field crossfire method of Gauss. We use Coolidge and water-cooled Roentgen tubes. As the vacuum or hardness obtainable in the water-cooled tubes is higher than in the Coolidge, we prefer the former. However, the use of the water-cooled Roentgen tube involves a greater expenditure in the duration of the exposure, but the higher vacuum obtainable insures a deeper penetration. This, after all, determines the preference for the water-cooled tubes.

Thirty to fifty erythema doses are necessary to destroy a malignant growth within two centimeters of the surface of the abdominal wall. It requires seven times this amount, that is three hundred and fifty erythema doses, to remove metastases near the posterior pelvic walls, which are about ten centimeters distant from the surface of the skin of the suprapubic region. The Roentgen tube should have a hardness of twelve to thirteen and a half, as determined by a Wehnelt penetrometer. It should carry a critical current of four to five milliampères. The constancy must be maintained for an indefinite length of time by a continuous flow of cold water around the anode and an interruption of the current for a half second out of every second while in use to keep the tube cool, and thereby retain the originally indicated hardness. The latter should be controlled by a Heinz Bauer qualimeter. The distance of the anode from the body should be 21 cm. The rays must be filtered through a three millimeter aluminum screen, to exclude the soft rays. Under these conditions, ten to twelve erythema doses may be obtained per hour. If three séances of one hour each are given daily, ten to fourteen days are necessary to reach an amount of three hundred and fifty erythema doses. We use six fields as portals of entrance, and must apply about sixty erythema doses to each field. Bumm does not hesitate to apply one hundred erythema doses to a field.

The time of exposure may be reduced by using a Coolidge tube. L. G. Cole states that an erythema dose may be filtered in one minute using a three mm. aluminum filter. The entire application of three hundred and fifty erythema doses could, therefore, be made within six hours.

The Possibility of Increasing the Intensity and Penetration of the Gamma-rays of Radium by Excochleation and Cauterization of the Cancer Growth.—The distance between the radium capsule and the periphery of the tumor may be decreased by the removal of the cancer tissue with the sharp spoon and the cautery iron. Thereby the intensity and penetration of the gamma-rays in the peripheral portion of the tumor is markedly increased. This method is especially practicable in the proliferating cauliflower growth of the cervix. Cauterization has been performed in every case in our series, in which such a procedure was not otherwise contraindicated. The result is a marked reduction in the extent of the new growth and a corresponding increase in the penetration of the rays and a decrease in the duration of the exposure of the gamma-rays. It is a purely economical question and has no other influence on the result of the radium treatment.

It is advisable to perform a colostomy in rectal cancers. This renders the seat of the carcinoma clean, prevents absorption of septic and putrefactive material, gives the patient an invaluable relief and makes the use of radium less obnoxious to patient and surgeon.

In vesical cancers in the male, a suprapubic cystotomy should be done. The radium may then be inserted through the suprapubic drainage tube. Injury to the posterior urethra by long-continued insertion of a cystoscope is avoided, the use of an operating cystoscope becomes unnecessary, and the objections on the part of the patient are obviated. However, the catheter procedure, as before mentioned, may also be used after a preceding dilatation of the urethra, so that a cystotomy can be avoided.

The Histological Findings.—The histological changes may be divided into four stages:

The first stage is characterized by an enlargement of the carcinoma cells, a hyperchromatosis and a pycnosis of the nuclei. They are evident in all the cases examined. These changes usually occur within about ten days after the first application of radium.

In the second stage we observe caryolysis, caryorrhexis, cyctolysis, and cell detritus. They are seen as early as from the first to the third week of the treatment.

The third stage shows an absorption of the cellular and nuclear debris by phagocytosis. Macrophages and microphages are concerned in this step. It takes place as soon as the cells begin to degenerate.

The fourth stage is the stage of connective-tissue proliferation and scar formation. It completes the histological cure of cancer. The places left vacant by the dead carcinoma cells are immediately filled by young fibroblasts derived from the connective-tissue stroma of the tumor. The fibroblasts become differentiated. The fourth stage appears usually after the first to the third month, but may occur much sooner.

A discrepancy frequently exists between the clinical results and the histological findings. For instance in case 26 of our series there was evidence of a completely destroyed cancer tumor, yet the patient succumbed to a bowel invasion, proving that some cancer cells either remained uninfluenced by the radium or regenerated after the subsidence of the action of the rays. Therefore, certain questions arise which call for definite answers before we may positively state that radium rays cause a degeneration and ultimate death of cancer tissue and a simultaneous proliferation of connective tissue.

1. Are we able by microscopic examinations to differentiate the necrobiotic changes in the carcinoma cells brought about by natural and artificial conditions from those caused by the influence of radium rays? Cells undergo necrobiotic changes in the course of their existence. Heat, caustics, and alcohol, brought in contact with the tissues, may produce the same changes, as is well known. However, the absence of cell degeneration as evidenced in the first section, and the general and extensive changes as seen in the subsequent specimens after their exposure to the gamma-rays, and the regularity of their occurrence in all the tissues microscopically investigated, even in those not previously cauterized, permit us to state that they must be caused by the action of the gamma-rays.

2. Can we, by examination of small pieces of tissue removed from the growth, determine the extent and intensity of the action of radium rays? We cannot from such an examination, but could do so from serial sections from all the organs removed either intra vitam during operations or, preferably, post mortem.

I have, fortunately, seven cases in which an abdominal panhysterectomy was performed after a clinical cure of the cancer by the use of radium rays was obtained. (Cases 26, 29, 32, 64, 128, 162, and 165.) Serial sections were made from the tissues removed. A microscopic examination revealed that the cytolytic changes were generally present throughout the tumor. This does not prove that distantly located foci were not left behind. As a matter of fact, patients 26 and 29 died subsequently from cancer. This shows that viable cancer cells were left behind somewhere in the pelvis. Bumm examined tissues acted on by gamma-rays and removed afterward during post mortem examinations. He estimated that the intensity of the gamma-rays sufficient to destroy carcinoma tissue extended into a radius of four centimeters. Within this area of intensity, carcinoma cells were not found present. Beyond it, however, typical unchanged cancer cell nests were still found to exist. In other words, extensive carcinoma growths are only partially destroyed by gamma-rays. This area of destruction, however, has a diameter of eight centimeters and enables us to reach tissues which a knife could never remove.

3. Is it possible by such microscopic examinations to state whether a carcinoma cell has perished or whether it might not regenerate after the action of the radium rays ceases? The following citation will illustrate the answer to this question. Créron and Rubens-Duval treated a patient suffering from an inoperable carcinoma of the cervix with radium during November, 1910, and January, 1911. The patient was apparently clinically cured. She died from an intercurrent disease (a cerebral softening) during April, 1912, fifteen months after the beginning of the radium treatment. All the internal organs and tissues were removed post mortem, and a careful serial histological examination of all the

tissues did not reveal a single carcinoma cell at any place of the organism. A complete anatomical cure by radium rays had been demonstrated.

I have made a similar observation in a case of Mrs. A. R., Augustana Hospital, number 44801, serial number 141, who was treated with 3,600 milligram-hours radium element from October 27 to October 31, 1915, for an inoperable cancer involving the cervix and the entire vagina. An examination made December 27, proved the patient clinically cured. She died suddenly during the latter part of January, 1916, from heartblock. The pelvic organs with the para and perimetrium and parietal peritoneum and lymphnodes, including the sacral, were removed *en bloc*. A most careful examination of stained sections in series did not reveal any cancer cells or nodules.

Our investigations demonstrate the uniformity and general extent of the necrobiotic changes brought about in the carcinoma cells by the action of the gamma-rays. Bumm's researches fix the extent of the area of intensity of the rays within which a carcinoma will become destroyed, and Chéron and Rubens-Duval's case proves the capability or efficiency of the radium rays to bring about an anatomic cure of cancer.

The Clinical Results.—The accompanying table gives the clinical results of thirty-five inoperable, twelve recurrent, and fifteen operable uterine carcinomata; seven inoperable, and three operable rectal cancers; and five inoperable, two recurrent, and one operable carcinomata of the bladder. The total number is eighty. They were treated between April 1, 1914 and April 1, 1916.

Carcinomata of Pelvic Organs Treated With Radium

The results of the radium treatment differ depending (1) on the organ involved and (2) on the stage of the disease. The prognosis is best in vesical cancers, less favorable in uterine malignant growths and least favorable in rectal carcinomata. The value of the treatment varies depending on the incurability, operability, inoperability or recurrence of the disease. Some cancers are far advanced and concealed and cannot be cured or improved by radium or any other remedial agents. The time elapsed in all the cases enumerated is too short to permit a discussion of the curative action of radium.

Inoperable Carcinomata.—Eleven clinical cures were obtained in thirty-five inoperable uterine, two in seven inoperable rectal and three in five inoperable vesical carcinomata. A clinical cure implies a complete subjective and objective cure of the cancer as far as this can be determined by an exact palpation and a microscopic examination. We have a total of sixteen clinical cures in forty-seven inoperable carcinomata, *i. e.*, 34.04 per cent. This percentage would have been higher if hopeless or terminal cases had not been included. However, we did not reject a single case referred for the treatment, regardless of the general condition of the patient. Twelve of the inoperable cases were far advanced and are included in these statistics.

The time elapsed since the beginning of the treatment in the fourteen clinical cures is as follows:

Serial No. 32, 26 months (hysterectomized); 69, 16 months; 98, 13 months; 113, 12 months; 140, 11 months; 128, 8 months (died from an intercurrent disease); 117, 2 months (died from an intercurrent disease); 141, 6 months; 162, 6 months; 165, 6 months; 150, 6 months; 170, 6 months; 168, 5 months; 178, 4 months; 70, 16 months; 153, 6 months.

The palliative action of radium in inoperable cases is truly remarkable. The three cardinal symptoms —hemorrhage, putrid discharge, and pain cease invariably within four to eight days after the commencement of the treatment.

There does not exist another remedial agent in our entire medicinal and surgical armamentarium, the application of which in inoperable carcinomata is followed by better primary and remote results. Radium will bring about this action without immediate or late danger to the patient provided the strictest asepsis and a perfect technique are employed.

Recurrent Carcinomata.—The primary results in recurrent cancers are: three clinical cures in fifteen uterine, and none in the two vesical cancers, *i.e.* 20 per cent.

The elapsed time since the beginning of the treatment is: No. 105, 12 months; 125, 10 months; 135, 9 months.

The prognosis of radium treatment in recurrent cancers is, therefore, not as good as in inoperable cases. Especial care is necessary in these cases to avoid injury of neighboring organs and contiguous tissues by the radium rays. As familiarity in the treatment of these cases increases the results should improve.

Operable Carcinomata.—The application of radium following radical excision of the uterus and adnexa for malignant disease is a purely prophylactic procedure. Carcinoma cells that have become spilled all over the wound surfaces during the progress of the operation or carcinoma cell nests and shoots that have been inadvertently left behind may become effectually destroyed by the gamma-rays. This fact has induced surgeons to increase the percentage of operability of their cancer cases on account of the possibility of subsequent radium applications following the radical operation. It also has rendered the operation less extensive, especially in the regions of the rectum and bladder because of

the evolution of radium-surgery. Cases No. 90, 101, 106, 133, and 188 were really inoperable, yet subjected to an abdominal panhysterectomy and subsequent radium treatment. Singularly enough the first three cases have done remarkably well, while the last two have not been benefited by the surgery and radium.

We do not wish to render an opinion as to the value of prophylactic radium treatment after excision of the operable cancers. The improvement or cure must be accredited to surgery. The time elapsed since the operations is too short to permit an expression as to a permanent or anatomical cure. The time passed since the operation and radium treatment of these cases is as follows: Serial No. 32, 15 months; 41, 20 months; 90, 14 months; 101, 13 months; 106, 12 months; 107, 12 months; 134, 9 months; 163, 8 months; 173, 4 months; 174, 4 months.

Conclusions.—1. The therapeutic action of radium depends on the use of a correct technique, which must be based on a careful physical examination of the patient and the physical properties and the biologic action of the metal.

2. The use of massive Roentgen rays, according to multiple field and crossfire methods in conjunction with radium therapy to destroy metastases, is an imperative necessity.

3. Certain surgical procedures must be used in radium therapy to assist the action and facilitate the application of the rays.

4. The action of gamma-rays on cancer tissue is specific and suggests positive proof of the possibility of destroying malignant tumors by the application of radium.

5. The results of radium therapy in inoperable and recurrent cancers surpass those of any other known therapeutic agent.

6. The prophylactic use of radium rays in operable carcinomata increases the percentage of operability and probably the efficiency of the operative procedures.

THE TREATMENT OF PARALYSIS AGITANS WITH PARATHYROID GLAND.

By WM. N. BERKELEY, A.B., PH.B., M.D.,

NEW YORK.

ATTENDING PHYSICIAN AT THE GOOD SAMARITAN DISPENSARY.

Numbers of inquiries from physicians interested in the study of paralysis agitans continue to come to me; and I have thought it might not be uninteresting to readers of the Medical Record for me to report briefly once more my therapeutic experiences with parathyroid gland. Since I last published anything on the subject in this journal, nearly six years have elapsed.[17] I can perhaps offer no better introduction than to repeat what I then said as to the physiological details involved.

"It may be briefly stated that when the parathyroid glands are removed from a dog or other suitable animal, a curious and characteristic train of symptoms follows,—hurried respiration, tachycardia, profuse salivation, twitching and shivering of the voluntary muscles, rigidity, intermittent convulsions, rapid wasting, and death. There is now an enormous literature on the subject. A fairly complete bibliography may be compiled from the writings of Jeandelise[1], Pool[2], Erdheim[3], Berkeley and Beebe[4], and Ochsner and Thompson[5].

"MacCallum,[6] in a further interesting and important contribution to the subject has shown that a suitable dose of a soluble calcium salt, injected into the veins of a dog that has been successfully operated upon in this way, will arrest the spasms and for a few hours restore the animal to a normal condition. He concludes that the parathyroid glands, therefore, preside in some way over the calcium metabolism of the body, and that the symptoms in question are caused by a deficiency of calcium. S. P. Beebe and I[4] have successfully repeated this experiment, which is one of the most striking phenomena in the physiological laboratory; from a series of additional experiments, however, we have been disposed to conclude that in such cases the calcium has a 'drug effect,' and that the parathyroid glands more likely furnish enzymes of prime importance in the intermediary metabolism of nitrogen. The subject is a difficult one and awaits further research.

"Whatever the ultimate solution of the physiological problem may be, such remarkable and characteristic symptoms strongly suggest some causal relation between a defective secretion of these glands and one or more of the known convulsive diseases, and medical men have not been backward in guesses of various kinds. Exophthalmic goiter was long ago proposed by Gley[7] and afterward given over. Vassale proposed puerperal eclampsia.[8] Epilepsy was first suggested by MacCallum (acknowledgedly in a tentative way),[9] but further independent researches by this author[10] brought him to the conclusion (reached about the same time by Pineles[11] and Erdheim (*l.c.*) and rather vaguely suggested by Jeandelise (*l.c.*) in 1902, four years previously) that *tetany* is the final answer to this long-standing question.

"Without going further into the extensive literature of this part of my topic, it will be enough to say that tetany—whether associated with surgical damage to the parathyroid glands in thyroidectomy, with infantile rickets, with pregnancy, or with dilation of the stomach—is unquestionably *one* of the answers. But a further inquiry remains whether this be the *only disease* having any relation to these glands; and it is now some years since the Swedish neurologist, Lundborg,[12] and I,[13] working along different lines, and each independently of the other, conceived the idea that *Paralysis agitans* is possibly due to some chronic disorder or disease of the parathyroid glands.

"In support of this hypothesis I have offered (*l.c.*) the following considerations: Paralysis agitans has all the marks of a chronic toxemia; the symptoms following parathyroidectomy are remarkably like those of paralysis agitans; in cases of myxedema and exophthalmic goiter, paralysis agitans has not infrequently occurred as a complication or sequela; of fourteen reported autopsies on paralysis agitans, two by Erdheim (*l.c*) and nine by R. L. Thompson,[14] showed negative parathyroid glands, but two by C. D. Camp[15] and one by myself[16] showed distinct pathological changes; and lastly a remarkable percentage of cases of paralysis agitans treated with properly identified fresh gland, or a properly made extract, have been greatly benefited."

As a source of supply for the remedy, the parathyroid glands of the horse are available in those countries where horse meat is a popular flesh food, and where horses are slaughtered in well-conducted and officially inspected abattoirs. In this country

the only glands generally available are those of the bullock. As regards methods of preparation, I have elsewhere remarked on the careless and unscientific way in which the ordinary parathyroid of commerce is prepared, and I have mentioned the successive experiments through which I have labored in order to get a preparation which more nearly represents the unmodified gland.

I have used fresh glands with some success. A medical associate writing me some years ago from Ohio told me of an elderly lady fed on fresh parathyroid whose improvement was quite marvelous, and lasted over the entire time (about two years) during which she was under observation. But fresh glands are very expensive, are not permanently palatable, and are, of course, not accessible to the great majority of patients.

Later on I made a long series of experiments with crude gland rubbed up with milk sugar, and dried. But this was indigestible, and it was found almost impossible to standardize it.

Much the best preparation is an acetic extract of the fresh glands (commonly though very inaccurately called a "nucleoproteid" extract), made by treating the ground or triturated glands with cold distilled water, filtering, and then precipitating with a very minute amount of acetic acid. I have fully described the process in several articles published elsewhere.[4, 18]

This extract, in doses of one-fiftieth grain (either in capsule with milk sugar, or as a hypodermic solution) is now for sale in a number of New York drug stores. It is not very expensive, and it comes nearer to the chemical constitution of the human gland than anything I have so far devised. It is absolutely without local effects of a disagreeable nature. Among hundreds of patients I have known of but one who either had, or thought he had, an idiosyncrasy for parathyroid. The hypodermic solution, in doses of fifteen minims, does not even redden the skin, if it be injected with reasonable care.

In the form in which I have recommended it, this remedy has been extensively prescribed during the last five or six years; the cases now number hundreds, and it has been successfully sent, so the dealers tell me, to all parts of the world.

Further experience seems fully to justify the opinion I have formerly expressed, namely, that parathyroid gland is not a "cure" for paralysis agitans, but that 60 to 70 per cent. of the sufferers from this dreadful disease who have given the remedy a fair trial for from three to six months (it takes all of this time to test it) have been greatly benefited, and that in such patients the progress of the disease has been arrested, or very materially retarded.

One patient, an elderly man, relative of a medical friend in the Bronx, has taken the capsules for seven years (also the hypodermic solution at times), and he is still in fairly good condition, but lapses into helplessness within a few days when the medicine is omitted.

Another recent case, woman, 52 years old, brought to my clinic by Dr. Leon Lesser of Brooklyn, has done wonderfully well on my formula. Her agitation has been entirely arrested, and her rigidity greatly relieved. She had suffered with the disease for two years before I saw her, and had spent all of her money on osteopathic and electrical treatments; so that, if suggestion had anything to do with her case, she certainly had ample opportunity for full exercise of her imagination before undertaking the parathyroid medication.

There are no other internal secretions which have any specifically beneficial effect whatever—either alone or in combination—in paralysis agitans. Among the older patients pineal gland is a useful stimulant to functionally failing mental activity, and there is now on the market one extract of pancreas which is valuable in the peculiarly obstinate constipation these patients are afflicted with. But I cannot too strongly deprecate promiscuous dosing with thyroid, and pituitary, and others of the internal glands. Thyroid, especially, does serious harm; even massage of the neck over the thyroid gland sometimes liberates enough of the thyroid secretion to make the patient distinctly uncomfortable.

Like most chronic diseases, paralysis agitans does not do well in institutions, for reasons which are sufficiently obvious. The most successful cases have been in private practice, where cheerful surroundings, occasional opportunities for travel, and a varied diet contribute to the patient's comfort, and increase his resisting power. But a fair proportion even of the almshouse poor have been greatly helped.

I am still of the opinion, as I have long been, that paralysis agitans is caused by a deficiency of the parathyroid glands, and that further and more diligent study of the complicated chemical processes involved will make it ultimately possible to cure paralysis agitans with parathyroid in just the same way in which cretinism is cured with thyroid.

Psoriasis as a Sequel to Acute Inflammation of the Tonsils.—Wingate has now seen six cases of this sequence which he is unable to explain, there being no evidence of an infection. In four cases there was ordinary follicular tonsillitis, and in a fifth streptococcus sore throat. The sixth case followed an extirpation of the tonsils. None of the familiar throat organisms has ever been known to cause psoriasis. The only remaining view is that the balance of metabolism was somehow disturbed, either by the fever or the state of the tonsils.—*Journal of Cutaneous Diseases.*

THE WASSERMANN REACTION.

By B. LEMCHEN, M.D.,

DUNNING, ILL.

With the introduction of the complement fixation test we have obtained something valuable in diagnosis. It is hardly necessary for me to comment on this. The reason I am writing this paper is to try to make it clear that there is some misunderstanding about the test, because in some cases where the test should be positive we get a negative or *vice versa*, and because the same serum or fluid gives different results in different laboratories. Some physicians try to disregard the test entirely. It is with the Wassermann test, as with everything else in medicine, the value increases with the knowledge thereof.

First of all, it must be understood that the Wassermann reaction is a biological phenomena and it confronts everything else in biology. Biology deals with life, deals with a mystery, because the molecular arrangement of the living cell is not known to us yet. It is a question whether it ever will be known because every living cell must be killed before it can be analyzed; but as little as we do know about biology we know this much, that life in higher planes and in animals depends on two things, one is an attack and the other is defense. Every higher form of life that cannot live on simple matter must attack another form of living cell to get its food. It must also defend itself against another living organism that is trying to live upon it, and to keep up this species a third factor comes in and that is reproduction; so I might state that attack, defense, reproduction are the foundations of the living organism. They are also the source of all evils, the reason a crime is committed, because one can trace the crime to either attack, defense, or reproduction. They are also the root of insanity.

Why does a paranoiac kill? He has imaginary enemies. It is a defense reaction. He believes that some people are organizing against him to try to ruin his life and his family and, after trying every possible way of defending himself believing that he has not succeeded, as a last resort he kills his enemy. Why does one in delirium jump out of a window? Practically the same thing. It is a defense reaction. The patient in his delirious state sees different animals trying to jump on him to tear him to pieces, he has only one way of escape and that is to jump through the window. What else should he do? So he jumps through the window. We might also say that catatonia is also a defense reaction, as it 's known that lower animals, when they are in great danger of being caught as a prey by stronger animals, lie down motionless. Therefore, it is not strange that human beings when they are overcome with fear are practically paralyzed and cannot move.

Why does a dementia precox subject strike impulsively? It is due to the inheritance of attack. We can also understand mannerisms and dream states by the inheritance reproduction. Now it is understood always that in the animal kingdom it is the stronger animal that attacks the weaker. It is the weaker that has to defend itself against the stronger, but there might be a time when the stronger animal was weakened either by disease or by not having sufficient food, in which event the stronger animal would have to defend itself against the weaker animal. It is also known that the animal reproduction goes hand in hand with the strength and life of that animal. An animal might be so weakened that he could not reproduce any of his own kind.

Now, we shall apply all these facts to the Wassermann reaction. It will not explain everything, but it will explain a good deal. The Wassermann reaction is also due to the same phenomena of attack and defense. Here it is *Spirocheta pallida* that is attacking and it is a human being that is defending against the attack. The same rule is holding true here. *Spirocheta pallida* is an organism that has to have albumin to live. It is also a species that is reproducing its kind or multiplying itself. It attacks a human being because, so far as we know, it cannot live in any other media but the human tissues. It produces toxin which weakens the human beings so it can attack them more strongly. A human being has to defend himself against it, and nature has provided help for defense against microorganism by producing something known as antibodies. Here again *Spirocheta pallida* is a living organism and besides being able to attack it is also able to defend itself. It likewise produces something that will neutralize the antibodies. Here, again, the one that is infected with this *Spirocheta pallida* will have to produce more antibodies to defend himself against the organism. The *Spirocheta pallida*, as regards its growth, its reproduction, its power of producing toxins, etc., is influenced by the food it is getting. There might be a medium that is favorable for its life, but it would not be favorable for reproduction. There might be a medium favorable for its growth, but not capable of producing toxin.

Now, let us apply all we know on the Wassermann reaction and see if we cannot explain everything regarding what we have said. The Wassermann reaction is due to the fact that antibodies will unite with their specific antigens; but the antibodies are composed of two substances, one that is comparatively stable, that is not destroyed by heating to 56° C., and the other known as the complement, that is unstable, and is contained in all blood serum and is destroyed by heating to 56° C.

Wassermann takes antigens that are supposed to be products of the *Spirocheta pallida*. Lately it has been found that lipose from any organ will answer the purpose. He takes a certain amount of this and a certain amount of the blood serum of the patient to be tested, after the complement has been destroyed by heat, and a certain amount of antigens. To these he adds a certain amount of complement, which he takes from the serum of a guinea pig and incubates them for about an hour. Then he adds to this a certain amount of red blood corpuscles from the sheep and a certain amount of blood serum from rabbits that have been sensitized against the red cells of sheep, the complement of which has been destroyed by heat. He incubates them again for about an hour and then examines the tube. If the patient has syphilis the complement will have been fixed at the first incubation and there will be no hemolysis, but in case the patient does not have syphilis there will have been no union between the antibody and antigens and the complement will be free to react with the red cells from the sheep and the rabbit blood serum, and there will be hemolysis. Now, we can readily see why results should vary.

First, it takes some time before the patient will react to the toxins of the spirochete. For this rea-

son, at the beginning there are not enough antibodies to give the reaction, but after a couple of months, there are sufficient antibodies and we get the reaction, generally in from three months to a year. The Wassermann is practically positive in syphilitic cases in more than 90 per cent. Now, as I said before, the spirochetes are able to defend themselves by producing something that will neutralize the antibodies. If there is sufficient of that something to neutralize the antibodies, the reaction, of course, will be negative. It is a fact that in old syphilitics we do not get more than 50 per cent. positives, probably less. Again, there might be antibodies still free, but not as many, and for this reason we will get a positive reaction in larger amounts. It is also a fact that old syphilitics include Tabes. When we do not get a positive reaction in the ordinary amount, which is 0.2 c.c., we may get a positive reaction in 0.5 c.c. or 1 c.c. Again, the patient may be so weakened by the disease or other diseases that he cannot defend himself or, which is the same, cannot produce antibodies; then we shall get a negative reaction even in a syphilitic. Again, the media may be so altered that while the organisms may still retain their power to grow they may lose their power of attack or defense. In case they lose their power to attack but retain their power of defense, they will not liberate anything to stimulate antibodies but will still liberate substances to neutralize antibodies; or they may lose their power to produce substances to neutralize the antibodies but will liberate toxins which will stimulate the production of antibodies. It is also known that by treating the patient, for instance, with salvarsan or mercury, a positive reaction may become negative or a negative reaction positive, while the spirochetes will still grow and multiply. This will also explain why the same serum may give different results in different laboratories, as it is evident from what has been said that antigens will vary according to the source from which they have been taken.

Again, we know that antibodies can be transmitted from the mother to the fetus, and it is also known that children who are born from syphilitic mothers seldom contract syphilis, although they themselves never have signs of congenital syphilis. Now there are some investigators who claim that they do have syphilis because they give a positive Wassermann reaction, but this I do not agree with. So long as a child does not show any signs of syphilis he has not got syphilis, but the positive reaction is due to the transmission of the antibodies from its mother either through the placental circulation or through the milk when nursing.

I wish to state that in my opinion the reason we never could find a substitute for mother's milk for babies is due to the fact that nature has provided for the helpless infant, that his mother should supply him not only with nourishment but with the invisible defense against infective bacteria. It is known that the majority of the antibodies belong more or less to the ferments, and the ferments are destroyed by digestion, and nature has so fashioned the infant's stomach that it absorbs some albumins from the mother's milk without the necessary digestion, while the milk of other animals has to be first digested before it can be absorbed. This is the reason why we have so much trouble with modified milk.

Again, Finger has demonstrated that the spirochetes can be transmitted by the spermatozoa, so it can easily be seen that when a woman gives birth to a syphilitic infant that has been infected by his father, the placenta prevents the transmission of the organism to the mother, while the antibodies can be transmitted, so the woman might receive antibodies from the fetus when she, herself, may never be infected with syphilis. It has also been known for a long time that a syphilitic infant will infect the strongest nurse but will never infect its own mother; this is what is known as Colles' law. Here again, some investigators claim that the mother does have syphilis, because she often gives a positive Wassermann. I disagree here, also. It is known that mothers have lived for years and years and never shown any manifestation of syphilis, never being infected by their syphilitic children. I say that the positive Wassermann reaction is due to the fact that the mother has received antibodies from the child but has never had syphilis.

In conclusion let me state that I consider the Wassermann reaction to be of the greatest value in the diagnosis of syphilis, but it must be taken into consideration with the other known manifestations of the disease. We should not make a diagnosis entirely on the result of a Wassermann, we should not declare a patient free from syphilis because his Wassermann was negative, and the physician should be careful in declaring a patient who has had syphilis free therefrom because the Wassermann is negative after treatment. If there are any signs that the nervous system is involved, a spiual puncture should be made and the spinal fluid examined by the cell count, globulin test, and also Wassermann reaction. If 2 c.c. gives a negative result, we should try with larger amounts.

Chicago State Hospital.

The Alcoholic as Seen in Court.—Victor V. Anderson has made a study of 100 cases of chronic alcoholics, those who are repeatedly arrested for drunkenness and seem more or less unmodified by any form of treatment. He gives statistics with reference to the number of arrests, the economic efficiency, the mentality, and the diagnosis in this series and finds that not more than one-half were capable of supporting themselves out in society. Fifty-six per cent. had the mental level of children below the age of twelve years. They were all suffering from conditions in general regarded as medical problems. For purposes of treatment they, in general, fall into two classes, namely, the steady drinker and the periodic drinker. The mentality of the former is either defective to begin with, or is so deteriorated from the insidious effects of alcohol as to require that he be confined or have prolonged care and hospital treatment. The periodic drinker, though in many instances he may require short periods of detention, as well as hospital treatment, is in general to be handled on probation and incorporation into society's scheme of living by means of well-directed medical, psychological and social service methods of treatment, methods that take full account of his peculiar mental make-up, his character defects, and temperamental difficulties.—*Boston Medical and Surgical Journal.*

A General Plan for a Schedule of Medical Fees.—J. N. McCormack makes some suggestions which are in part as follows: Day visit in town, $2.50; night visit in town, $4; ordinary office examination, $1; complete examination with advice, $5; advice or prescription by telephone, $1; obstetric case, uncomplicated, not over 6 hours, $15. Cases seen in consultation, double fee. Fees in the country are regulated as usual by mileage, while no fees are tabulated for surgical and other special work.—*Kentucky Medical Journal.*

New York, July 15, 1916.

PSYCHIATRIC TREATMENT OF SOLDIERS.

THERE seems to be a certain amount of conflict of opinion as to the effect on the nervous system of soldiers fighting in Europe, of the unprecedented conditions of warfare existing there. It was freely predicted at the outset of the war that the present generation of young men and especially of those of England and France whose vital energies were said to be sapped by city life and self-indulgence would inevitably break down under the fearful strain of war. The conditions of war have been worse than anticipated and it appears on the whole that the fighting men have borne up very well under them. Some say that affections of the nervous system have been infrequent, while others declare that a large proportion of soldiers are incapacitated by such disorders. Perhaps the truth lies in the mean.

In a special bulletin issued in April, 1916, by the Military Commisson of Canada, Dr. C. R. Clarke of Toronto discusses the psychiatric treatment of soldiers. According to this authority, the question of caring for returned soldiers suffering from mental and nervous troubles has engaged the attention of the Canadian medical profession in a marked way since the actions of last year. He points out that new conditions have arisen since the use of high explosives and the mental strain during action seems to be of the most severe character, with the result that numerous such cases are encountered requiring special treatment.

With regard to the manner in which such patients should be treated, the writer emphasizes the fact that neither convalescent homes, general hospitals, private houses, nor asylums are appropriate places in which treatment may be carried out. As convalescent homes and general hospitals are obviously unsuitable for the treatment of these cases, under the present conditions cases of marked mental trouble, although curable in the majority of instances, have to be sent to asylums. Of course, this is most unfair and, in a manner of speaking, a tragedy, for not only does it place upon the men the stigma of being certified inmates of a hospital for the insane, but perhaps in the majority of cases it precludes the possibility of successful treatment. In the large proportion of cases proper and intelligent treatment will cure, while it is equally as obvious that unintelligent and careless treatment will tend to aggravate the mental state, and life in an asylum is apt to have the most dire results.

As Clarke says, modern methods demand that recent cases of mental disease should receive just the same attention that cases in a general hospital secure. What should be done is to acquire a house of suitable structure which will afford accommodation for a certain number of patients. The necessary staff is best lodged in a separate building. This hospital should be equipped with the most modern scientific, hydrotherapeutic, and electric apparatus demanded in the care of such patients, and especially should the medical attendants be men who have been well trained in the diagnosis and treatment of mental disorders. This, after all, is the most important point. If a correct diagnosis be not made, the patient will not be treated as he should be treated, and a medical man to be able to make a correct diagnosis must be an expert. Also nurses should be specially qualified and should be women of the highest type, as on the sensible nursing of psychiatric patients the outcome largely depends.

During recent years it has been increasingly evident that in order to treat mental disorders intelligently new methods must be devised. Some men are peculiarly fitted by temperament and order of brain to deal with such cases, and these men should be rendered as skillful as possible by long training. We are only now on the eve of managing mental affections in a sensible manner, and the war in Europe will, it is to be hoped, tend to develop a really scientific system of differentiating between the various kinds of mental aberrations and of treating each kind on its merits, or rather in the way that its peculiarities call for.

SWIMMING-POOL SANITATION.

IN large cities the question of supplying adequate swimming-pool facilities, and their sanitation, is a very pertinent one. Because of the mode of living, especially in the congested districts, this offers really the only means of sufficiently cleansing during weather when this seems most necessary, besides offering the readiest, though temporary, relief from the depressing heat of the summer months. It is for them a stimulant of first value in overcoming the relaxation and the exhaustion accompanying such weather. At least for bathing and cleansing purposes, the pool—or its prototype in miniature, the bathtub—method is entirely unsatisfactory because it entails rewashing in the water contaminated by the very materials one desires to get rid of by the bath. At best, this method is unsanitary, and the sooner all pools and tubs are replaced everywhere by the shower bath the better. If this is properly and not extravagantly used, the consumption of water may be very small.

In cities like New York, situated on tidal water, the use of stream pools for bathing purposes in the summer is a universal practice. The question of the safety of these stream pools is most important, especially when the waters are depositories for sewage. Even the tidal waters surrounding such a city as New York are not sufficient to remove the enormous amount of sewage deposited. While ordinarily the typhoid-colon element in water is not a large one, because usually so soon and so much diluted, where there is bathing at the very

points of discharge of the sewage, the danger to health is great, especially in respect to the spread of typhoid where there is a large carrier population. Moreover, the whole gamut of pathogenic bacterial infection can be spread by pool water. Epidemics of vulvovaginitis, venereal disease, aural and ocular conditions have been reported as having been spread by swimming pools.

As a later development in swimming pools, the indoor pools offer a great many advantages, and obviate the prolific source of infection carried by live sewage. The usual drinking water being used, the opportunity for infection is only that of drinking water, and to a much lesser degree if the water is kept fresh and wholesome by one method or another. The element of colon contamination is supplied almost entirely by the bathers themselves, the dilution depending upon the amount of fresh water added, and the frequency of the addition. Investigations carried on by Manheimer (Public Health Report No. 229) showed that this element of pollution was quite appreciable. He made the amount of the bacterial content of the water and the presence of colon bacilli as his bacteriological index of the purity of the water, and the clearness and the ability to see the bottom of the pool as his practical index, being especially the index of the amount of solid matter suspended in the water. The larger the pool capacity in relation to the daily attendance, and the greater the frequency of the change of the water the safer is the pool. The least expensive and the best method of maintaining pool sanitation is by refiltration of the water used, combined with some chemical treatment, usually a coagulent like alum or calcium hyperchlorite. When the latter is used, a trace of chlorine must always be present in the water to make it adequate.

The installation of indoor swimming pools, as recommended by the New York Department of Health, will soon take the place of the highly unsanitary stream swimming pools. But the installation must be along proper lines as to capacity, attendance, refiltration, and chemical treatment, else all the good that might accrue from the indoor pool will be lost.

THE COLD FEET OF LEGISLATORS.

THE Romans did not believe that a man possessed the capacity for making laws to govern other men until he had learned to govern himself, *i. e.* until he was long past the follies of youth, or until he was what we would call aged. It is not recorded, however, that their laws were any the less just or their public policy any the less martial because their circulation was less vigorous than in youth. Cold feet may exist actually then without their supposedly concomitant mental attitude.

In an article dealing with "colds," in the *British Medical Journal* for April 15, Dr. Leonard Hill calls attention to the ventilation of the House of Commons, where the ventilating current is driven up through the floor in such a way as to cool the members' feet, while their heads are exposed to more stagnant air. As a result, Hill says, they suffer from cold feet and stuffy heads; he does not say whether or not he uses these expressions figuratively. In the May 13 issue of the same periodical Dr. E. Lloyd Owen takes exception to Dr. Hill's theory. He believes that, warm feet and a cool head being the ideal conditions to promote sleep, cool feet and a warm head must necessarily make one wide awake, which is ingenious, but savors too much of sophistry. Dr. Owen says that he finds difficulty in thinking after spending eight hours in a warm bed; that is, if he remains in bed. This is susceptible of another explanation. Having spent eight or nine hours in a warm bed, the apposite idea would naturally be to arise, hence the disinclination to think at all.

Whether, then, we believe with the pacifists in cold feet for legislators, or think that, come what may, a lawmaker should have a cool head at all times, whether his feet be frying or freezing, we will all agree that the subject of ventilation of legislative halls should be given enough attention so that the soporific effect of carbon dioxide is not added to the somnolence of the spoken word.

THE PRESERVATION OF CERTAIN ANTIGENS.

THERE are a number of difficulties which arise in the attempt to produce anti-human precipitin rabbit serum, a procedure which may be of the greatest importance in a medicolegal connection. The need for haste may be imperative, the rabbit may die at the critical moment, from anaphylaxis, from peritonitis, or, from the toxic effects of the serum, and it may be difficult to obtain the human serum in the desired quantities at the desired time. Efforts to preserve the serum in fluid form have not been very successful since it shows a tendency to precipitate a portion of its protein content even though sterile and kept at a low temperature. It would doubtless be possible to keep it unchanged when frozen and dried *in vacuo*, but the technique of this method is quite laborious and requires special apparatus.

In order to avoid, as far as possible, most of the difficulties above mentioned, Smith *(Jour. Med. Research*, 1916, xxxiv, 169) has made use of the precipitate obtained by treating the human blood with ammonium sulphate. The sediment thus obtained is freed from the solution by prolonged and vigorous centrifugation. The precipitate is then dried, powdered, and put up in tubes each of which contains 0.5 gram, representing the sediment from 10 c.c. of blood. Before use the powder is taken up in 2 c.c. of sterile salt solution and is then ready for injection. The small amount of ammonium sulphate remaining proved slightly irritating when the material was injected intraperitoneally and markedly so when it was injected into the vein. It would probably be necessary to remove this salt by dialysis before using the preparation intravenously. This material proved to have active antigenic properties, even when nine months old, and the serum produced from its use was uniformly of good value. It is necessary to use a very small bulk of the substance and its administration is apparently without danger. Such a preparation would be of great help at times and it offers a convenient way for the storing of the antigen. The author used placental blood and thus

was able to obtain a large volume with but little difficulty. It is probable that a similar method may be applied to a number of the immunological reactions for the preservation of the reagents.

Medical Preparedness.

There has recently been organized a Committee of American Physicians for Medical Preparedness, representing the American Medical Association, the American Surgical Association, the Congress of American Physicians and Surgeons, the Clinical Congress of Surgeons of North America, and the American College of Surgeons, which in cooperation with the Federal Government is formulating plans for the purpose of ascertaining, organizing, and utilizing the civilian medical resources of the country in accord with the comprehensive plans for national defense which are now being carried out in all lines of endeavor. The chairman of the committee is Dr. William J. Mayo, and the secretary, Dr. Frank F. Simpson, Jenkins Arcade Building, Pittsburgh, Pa. The first duties of the committee will be to aid the medical departments of the United States Navy and Army by making a comprehensive inventory of the qualifications of individual civilian physicians throughout the country, and to cooperate with the American Red Cross in bringing that organization up to the highest standards of medical ideals and in forming Red Cross units throughout the country. As it is the desire of the Surgeon-General of the army greatly to increase the number of medical men in the Reserve Corps, the committee will also endeavor to interest the medical profession in that branch of the service, if Congress will permit it to survive. The organization will include, in addition to the national committee, committees of nine members in each State.

Fancy-work for Surgeons.

Who of us has not sat admiring the deft way in which a wife or sister or one who has not promised as yet to be either makes a needle fly back and forth through a piece of linen until the line of stitches seems actually to grow under our eyes by leaps and bounds? And then we have contrasted mentally the surgeon at the next operation we witness, excellent workman though he may be, watching him crunch down upon a needle with a needle holder, push a needle the size of a darning needle through the tissues, release the needle-holder, seize the needle again on the other side and so on, wishing that a little of the seamstress's dexterity might be communicated to him. Or perhaps we are surgeons ourselves and have often wondered what an efficient expert would say to the countless lost motions in the sewing up of an abdomen.

And yet the answer is easy. Simply a course in sewing, plain and fancy, but above all a few lessons in the correct way to use a thimble. Sit at the feet of some good housewife and learn the fundamentals. Dr. Edward Harrison, in an article in the *British Medical Journal* for May 6, gives this excellent advice, illustrating by his own experience. He began six or seven years ago to learn to sew with a thimble and gradually advanced until he was able to hem a fine cambric handkerchief accurately and fairly rapidly. Applying this accomplishment to his surgery, he found his needle much more easily directed and managed almost entirely with one hand, leaving the other free to expedite the work in some other way. Dr. Harrison found that he could use a straight needle for many kinds of suturing where it was generally supposed only a curved one could be used.

In these days when our patients, especially those who affect décolleté, demand the invisible scar and other cosmetic results of operations, the suturing of the wound plays a much greater part than it did years ago, and a suggestion such as that of Dr. Harrison is worthy of serious attention, in spite of the smile it may evoke at first. Let us not forget also that the beneficent effect of the operation itself may in some cases depend almost entirely on the skill with which the parts are approximated and not neglect anything which might enhance that skill.

A Question of Anatomy.

As was to be expected the *Journal of the American Medical Association* has attacked editorially Dr. H. H. Rusby of this city because of the testimony he gave in favor of the plaintiff in a libel suit recently decided against the Association. We are not going to defend Dr. Rusby, who needs no defense, for a lifetime of honorable service in the cause of science speaks for itself. It pains us, however, to find our esteemed contemporary wrong also on an anatomical point. It speaks of "Dr. Rusby's weird conception of the anatomy of the female pelvis," because he referred to "the unstriped muscular fibers of the broad ligament!" (mark of astonishment the *Journal* editor's), and advises him, when he gets back to Columbia University to "ask a freshman student in the anatomy class to make a dissection of some of the unstriped muscles in the broad ligament." The funny point here is that the broad ligament does contain unstriped muscular fibers, as Cunningham, Gray, and all anatomists, as well as De Lee and many obstetricians, testify. Whatever the wants of others may be, Dr. Rusby evidently needs no freshman to teach him anatomy.

News of the Week.

Troops' Health Cared For.—Three of the best sanitarians of the army, Lieut.-Col. Edward L. Munson, and Majors R. B. Miller and W. N. Bispham, have been sent from Washington to San Antonio to take charge of the organization of the sanitary forces along the Mexican border. Dr. Thomas Darlington of New York also has been sent by the National Civic Federation to the border to investigate and report on the health of the enlisted men. The work of the Red Cross and of the army medical organizations has continued unabated during the week in spite of the loosening of the tension in the Mexican crisis. It is reported that a large percentage of the men who were in the organized militia at the time of the President's call have been rejected by the army surgeons for failure to meet the physical requirements.

Another Base Hospital Unit.—A letter has been received at the American Red Cross Headquarters in Washington from Dr. William J. Mayo, of Rochester, Minn., stating his willingness to organize a base hospital, the personnel and equipment of which will be furnished by the Mayo Clinic. The number of medical officers in a base hospital is 23; the number of beds 500, and the cost of the equipment is estimated at $25,000.

Camps for Doctors.—General Wood has an-

nounced that two training camps, both for medical men, will be held in connection with the regular Military Training Camp at Plattsburg, N. Y., during July. The course of instruction will cover camp sanitation and military hygiene, and the camps will be commanded by medical officers of the regular army. Enlistment blanks will be furnished by the Military Training Camp Association, 31 Nassau Street, New York.

The Poliomyelitis Epidemic.—Two hundred and eighty-seven deaths and 1440 cases was the record in New York City in the present epidemic of poliomyelitis up to July 12, by far the greater number of the cases and deaths having occurred in Brooklyn, where the first case was discovered. In its efforts to combat the disease the New York City Department of Health has received the help of all of the other city departments as well as of the State Department of Health and of the United States Public Health Service. The facilities of the last, offered by the Secretary of the Treasury, are a great assistance in the fight, and are being used largely to determine if possible the means by which the contagion is spread and the ways in which it can be controlled. The hospitals throughout the city have also responded to the call and practically all have offered to care for patients or to supply doctors and nurses for work outside. On July 9 the Kingston Avenue Hospital, Brooklyn, was filled to its capacity, 301 patients, and the Willard Parker Hospital, New York, with 139 patients had almost reached its limit. The use of the hospital on Swinburne Island containing forty beds was given by the Health Officer of the Port, Dr. L. E. Cofer, who also offered to supply doctors and nurses for twenty patients. The quarantine laboratory will undertake the routine diagnosis of all cases on Staten Island. By the passage of a special resolution through Congress it will be possible for the authorities of the city to use also the contagious disease ward of the Ellis Island Hospital in which 400 beds are available; doctors and nurses for the care of patients there, however, must be supplied by the city. In order to cover all this emergency work, the Mayor has authorized the sale of bonds up to $80,000. Practically all public places, moving picture theaters, etc., have been closed to children, the play streets have been abandoned, and the playgrounds have been thoroughly disinfected and will be kept as clean as possible. Parents are being advised by visiting inspectors and nurses as well as through the medium of moving pictures to keep their children as much as possible from other children. Cases of the disease have also been reported from many places in the State outside of New York City and also from Pennsylvania, Illinois, Missouri, Kentucky, Massachusetts, Wisconsin, Kansas, Iowa, and Indiana.

Brooklyn Dental College.—The committee which is soliciting funds for the establishment of a new college of dentistry in Brooklyn, to be conducted in cooperation with the Long Island College Hospital, announces that one-half of the necessary amount has already been subscribed; it is hoped that the college may be prepared to receive students and patients by next October. A dental infirmary for children and a clinic in oral surgery will be included. At present, Brooklyn has no dental college.

Medical Advance in China.—A public health department has recently been organized in the province of Kiangsu, China, in which Shangai is situated. The department will regulate food, drug, and sanitary inspections, as well as control home sanitation and medical education.

Floating Hospital Opens Season.—The first trip of the *Helen C. Juilliard*, the new floating hospital of St. John's Guild, was made on July 5, and a numbers of mothers and babies from New York and Brooklyn were taken down to the Lower Bay, where the boat anchored off the Seaside Hospital, New Dorp, S. I. The boat will continue to run each week day during the summer on a regular schedule. Tickets for the trips, which are absolutely free for sick babies, mothers, and children, are distributed through the various hospitals, dispensaries, nurseries, and like institutions.

Aiding the Red Cross.—A number of prominent physicians of New York City are serving on a special committee for the purpose of assisting the American Red Cross in its campaign to attain a membership of 1,000,000 throughout the United States. An appeal to the medical profession to join the Red Cross is signed by Dr. G. D. Stewart, Dr. G. E. Brewer, Dr. G. L. Gibson, and Dr. N. E Brill, representing the Red Cross Units of Bellevue, Presbyterian, New York, and Mt. Sinai Hospitals, respectively.

Home for Nurses.—A six-story home for the nurses of the Manhattan Eye, Ear, and Throat Hospital, New York, is to be erected on East Sixty-third Street, directly in the rear of the hospital building. The structure will have a frontage of 125 feet and a depth of 40 feet, and will, it is estimated, cost $300,000.

Merger of Journals.—The *New Orleans Medical and Surgical Journal*, which with the July number began its sixty-ninth volume, announces that the *American Journal of Tropical Diseases* has been incorporated with it, and that the combined journal, which will continue under the title of the former, will be the official organ of the Orleans Parish Medical Society and of the American Society of Tropical Medicine. One effect of the consolidation of the two papers will doubtless be to widen the area of circulation of the *New Orleans Journal*, which will be to the advantage not only of the journal itself but also and especially of the new readers of this old established and excellently conducted periodical.

Bequests to Charities.—By the will of the late Mr. Fredrick K. Trowbridge of this city the Flower Hospital, New York, receives a bequest of $5,000.

The Brooklyn Hospital and the Long Island College Hospital, Brooklyn, receive bequests of $2,500 each by the will of the late Miss Mary Baylis of that city.

Personals.—Dr. Harry Plotz and Dr. George Baehr of the staff of Mt. Sinai Hospital, New York, who have for over a year been studying the sanitary conditions, especially as regards typhus fever, in Eastern Europe, returned to this city on July 6.

Dr. E. V. Morrow of Portland, Ore., returned to this country recently, after having spent eighteen months as chief operating surgeon at the hospital at La Panne, Belgium. Dr. Morrow received from King Albert the decoration of King Leopold.

American Hay Fever Prevention Association.—The annual meeting of this association was held in New Orleans on June 15, when Dr. William Scheppegrell of New Orleans was re-elected president. Dr. Rupert Blue, surgeon-general of the Public Health Service, honorary vice-president, and Dr.

N. L. Thiberge of New Orleans, corresponding secretary. The president reported that thirty-four of the State boards of health had co-operated with the association in its campaign against hay fever, and that the research department had done excellent work in completing a list of the hay fever weeds for the Southern, Middle, and Eastern States, and was now preparing a similar list for the Western and Pacific States.

Pacific Coast Oto-Ophthalmological Society.—At the closing session of the annual convention held in Portland, Ore., on June 23 and 24, the following officers were elected: *President*, Dr. Clarence A. Veasey, Spokane, Wash.; *Vice-Presidents*, Dr. P. A. Jordan, San Jose, Cal., and Dr. Frank A. Burton, San Diego, Cal.; *Secretary-Treasurer*, Dr. L. D. Green, San Francisco.

Kentucky Valley Medical Association.—Officers were elected at the annual meeting at Richmond on June 29 and 30, as follows: *President*, Dr. Clarence H. Vaught, Richmond; *Vice-President*, Dr. Wilgus Bach, Jackson; *Secretary-Treasurer*, Dr. John H. Evans, Beattyville.

Women's Dental School.—The first dental school to be devoted exclusively to the training of women in dentistry will, it is now announced, be opened next month in connection with Hunter College (the New York City free college for women). There will be three terms of instruction, extending over a year, the first term beginning on July 10, and under the Seeley bill passed last April by the New York State Legislature, the students will be graduated as dental hygienists. Graduates of the school will be eligible for employment as dentists' assistants, as assistants in dental clinics, and as school inspectors under the Department of Health, in which case they will instruct the school children in the essentials of dental hygiene.

Conference on Eugenics.—The annual meeting of the Eugenics Research Association and the conference of the Eugenics Research Office were held at the Carnegie Station for Experimental Evolution, Cold Spring Harbor, N. Y., on June 23. Dr. Adolf Meyer was elected president of the association.

Philadelphia Medical Club.—At a recent meeting of the club a reception was held in honor of Dr. Charles A. E. Codman, president-elect of the Medical Society of Pennsylvania; Dr. John B. McAlister, the present president; Dr. George I. McKelway, president of the Delaware State Medical Society, and Dr. Alexander Marcy, representing the president of the Medical Society of New Jersey.

Hospital Sued.—Charging that six inches of rubber tubing was left in his body, after an operation three years ago, and that as a consequence he has suffered greatly, a former patient of Christ Hospital, Jersey City, N. J., has brought suit against the hospital for $20,000 damages.

Maine Homeopathic Medical Society.—The fiftieth annual convention of this society was held in Augusta, Maine, on June 12 and 13, when the following officers were elected for the ensuing year: *President*, Dr. Luther A. Brown, Portland; *Vice-Presidents*, Dr. Franklin A. Ferguson, Portland, and Dr. W. H. Walters, Fairfield; *Treasurer*, Dr. W. S. Thompson, Augusta; *Secretary*, Dr. Carrie E. Newton, Brewer.

Obituary Notes.—Dr. CHARLES S. WOOD of New York, a graduate of the College of Physicians and Surgeons, New York, in 1886, died at his home on July 6, aged 52 years.

Dr. WILLIAM BLUNDELL of Paterson, N. J., a graduate of the College of Physicians and Surgeons, New York, in 1861, and a member of the American Medical Association, the Medical Society of New Jersey, and the Passaic County Medical Society, died at his summer home in Allendale on June 30, aged 79 years.

Dr. ANDREW JACOB KOONTZ of Independence, Va., a graduate of the College of Physicians and Surgeons, Baltimore, in 1887, and a member of the Medical Society of Virginia and the Grayson County Medical Society, died suddenly at his home on June 20, aged 57 years.

Dr. JOHN F. W. WHITBECK of Rochester, N. Y., a graduate of the University of Pennsylvania, Department of Medicine, Philadelphia, in 1870, president of the medical staff of the Rochester General Hospital, and a former president of the Medical Society of the State of New York, died at his home on July 3, aged 72 years. Dr. Whitbeck was a fellow of the American College of Surgeons and a member of the American Medical Society, the Medical Society of the State of New York, the Monroe County Medical Society, the Rochester Pathological Society, and the Academy of Medicine.

Dr. WALTER JAY BELL of Atlanta, Ga., a graduate of the Medical Department of the Tulane University of Louisiana, New Orleans, in 1891, died at his home on June 17, aged 47 years.

Dr. I. R. AULTMAN of Meigs, Ga., a graduate of the University of Georgia, Medical Department, Augusta, in 1893, died at his home on June 22.

Dr. ROBERT J. GILLILAND of Easley, S. C., a graduate of the University of Maryland, School of Maryland, Baltimore, in 1883, and a member of the South Carolina Medical Association, and the Pickens County Medical Society, having at one time served the latter as secretary, died at his home, after a short illness, on June 26, aged 56 years.

Dr. LUTHER B. ETHEREDGE of Wagener, S. C., a graduate of the University of the South, Medical Department, Suwanee, Tenn., in 1900, and a member of the South Carolina Medical Association, and the Aiken County Medical Society, died at his home, suddenly, on June 24, aged 42 years.

Dr. JOHN P. CORRIGAN, formerly of Pawtucket, R. I., died at the Providence Hospital, Providence, from heart disease, on July 6, aged 59 years. Dr. Corrigan was graduated from the New York University Medical College in 1883, and practiced in Pawtucket until a few years ago, when he retired to join the Dominican Order, in which he was known as Brother Vincent. He was at one time a member of the American Medical Association, the Rhode Island Medical Society, the Providence District Medical Society, and the Rhode Island Ophthalmological and Otological Society.

Dr. PAUL PAQUIN, formerly of Asheville, N. C., a graduate of the University of Missouri, Medical Department, Columbia, in 1887, and a member of the American Medical Association and the Medical Society of the State of North Carolina, died at his home in Kansas City, Mo., after a long illness, on June 23, aged 55 years.

Dr. HEBER WHEAT JONES of Memphis, Tenn., dean emeritus and professor of clinical medicine in the University of Tennessee, Medical Department, and president of the Tennessee State Board of Health for twelve years, and of the Memphis Board of Health for eight years, died at his home, after a long illness, on June 26, aged 68 years. Dr. Jones was graduated from the University of Virginia, Department of Medicine, Charlottesville, in 1869.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

GENERAL MEDICAL COUNCIL—D.S.O. AND OTHER HONORS—CANADIAN ARMY MEDICAL CORPS—A GIFT TO LONDON CHARITIES—SILVANUS THOMPSON—NATIONAL HOSPITAL FOR EPILEPSY AND PARALYSIS.

LONDON, June 17, 1916.

THE General Medical Council in its five days' sitting disposed of a large amount of business, much of which, though necessary, possesses but little interest to the profession at large. Some of it, however, demands careful consideration by those who pay attention to it in this respect as well as to its relation to the public. The report of its education committee is of this nature. To it had been remitted the subject of the ethical relationships of medical practitioners, to the state, to their patients and to each other, with power to make any inquiries deemed advisable. A letter was sent to the teaching bodies which elicited the information that in most cases the subject is included in the courses of forensic medicine and public health, also to some extent in special lectures, but in many instances no attempt to deal with the subject has so far been made. The committee is of opinion that this neglect should not continue, though special arrangements may naturally vary among the different bodies. Accordingly they suggest that a general recommendation should be added to the resolutions of the General Medical Council dealing with the matter. Further, attention should be called to all explanatory notices issued by the Council on the subject.

Reports were also submitted by the University of St. Andrews, by the dental committee, the public health committee, the examination committee, the pharmacopœia committee, and the students' registration committee.

Capt. T. L. Ingram, R.A.M.C., has been awarded the D.S.O. in recognition of his gallantry and devotion to duty on the field. He collected and attended to the wounded under heavy fire, and from the beginning of the war has been conspicuous for his personal bravery on every opportunity.

The Military Cross has been conferred for gallantry and duty on the field on Capt. J. C. Brash, M.B. He went to an artillery dug-out which had had a direct hit, extracted the wounded and administered first aid under heavy shell fire. Capt. H. F. Percival Hart, M.B., Capt. Randall Woodhouse, M.B., and Lieut. W. J. Knight, M.D., for similar devotion under fire. The cooperation between the regular army medical service and members of the civil medical profession who have given their services to the army has largely contributed to the prevention of disease and the successful treatment of the sick and wounded.

A number of honors have been distributed on the King's Birthday. Among them some are of the profession. A P.C. goes to Dr. Christopher Addison. There are three Knights—F. Mark Farmer, Armand Ruffer, Nestor Tirard. K.C.M.G. is conferred on Baldwin Spencer; C.M.G. on Montizambert, Director-General of Public Health, Canada; Major Fred N. White, I.M.S., and Captain MacIlwaine, R.A.M.C. The Kaisar-I. Hind gold medal goes to H. M. Newton, F.R.C.S., Rev. P. Cullen, Brigade-Surgeon, I.M.S., retired, and Robert Geo. Robson, M.A., M.D. Several additions to the Order of the Bath and the Royal Victorian Order have also been made.

All branches of the medical services have lately received the highest commendation for their work both at the front and on the lines of communication. The sick rate has been low, no enteric fever, no epidemic. The results of exposure in the trenches in the winter were to a great extent checked by the precautions carried out. The Canadian army medical corps rendered most valuable assistance. The central laboratory and chemical advisers with the army took prompt action in investigating the gases and other new substances employed in hostilities and devising means of protecting the troops against their effects. The value of this work has been recognized in all directions.

A sum of £25,000, free of legacy duties, has been bequeathed by Mr. Frank Daniels to be distributed by the Lord Mayor of London among such charitable and benevolent objects as he may, in his absolute discretion, select, and in such proportions as he may think proper. Gifts to charity which are so absolutely free from restrictions are sufficiently rare to call for approving comment.

Prof. Silvanus Thompson died on the 12th inst., aged 65. He took B.A., London, in 1869, and proceeded later to the D.Sc., taking honors in science during the course. In 1879 we find him professor of physics at Bristol University College. In 1893 he was a delegate at Chicago Electrical Congress, at which he read a paper on Ocean Telephony. In this he put forward the idea of accelerating the speed of signaling in cables by the use of inductive shunts. He contributed many papers on a great variety of scientific subjects to the Royal and other societies, in some of which he served as president. He was honorary vice-president of the Electrical Exhibition at Frankfort in 1891. He was an able linguist; gave a lecture in Italian before the Volter Centenary Congress at Como, 1899, and one in German before the Urania Society in Berlin in 1901. He was author of "Lessons in Electricity and Magnetism" and other valuable works. He wrote the life of Faraday and of Lord Kelvin.

The National Hospital for Paralyzed and Epileptics has 68 beds for those suffering from shock and they are pretty constantly occupied by patients coming direct from the Expeditionary Forces and from Red Cross and military hospitals.

TREATMENT OF POLIOMYELITIS.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR: I make so bold as to offer the following suggestions regarding the treatment and prophylaxis of infantile paralysis:

Treatment—Local applications of 10 per cent. silvol or argyrol to the nose, with hexamethylenamine in large doses internally. The performance of lumbar puncture.

Prophylaxis—Silvol or argyrol to nose and hexamethylenamine in moderate doses internally in the case of all children who have come into contact with a positive case.

I base these suggestions upon the facts that the nose is probably the portal of entrance of the infection and that hexamethylenamine when taken internally will be found in the cerebrospinal fluid. Also, on the supposition that lumbar puncture will carry off some of the infecting organisms and their toxins.

1. The Etiology of Diseases of the Circulatory System.—Theodore C. Janeway discusses this subject under the tentative classification of known bacterial infections; probable, but unproved bacterial infections; syphilis (a) of the aorta, (b) of the heart, (c) of the smaller arteries; rare infections; parasites and tumors; intoxications, exogenous and endogenous; nutritional disturbances; mechanical disorders; nervous disorders; defects of development; hereditary disease and the relative importance of the various causes of myocardial insufficiency. He has tabulated the histories of his series of hypertensive patients previously reported with reference to past infections. The outstanding fact in this group is the frequency of a history of typhoid fever compared with pneumonia. A study of the statistics of Johns Hopkins Hospital from September 21, 1914, to April 2, 1916, leads him to the conclusion that no evidence has been brought forward to place hypertensive cardiovascular disease in the category of the direct results of syphilis, and that syphilis plays an indirect rôle, if any, in its causation. In discussing the rôle of alcohol in the production of disease of the heart or vessels he says there can be no doubt that the death rate from circulatory disease is considerably higher in those occupations where habitual drinking is the rule. However, a study of his own cases showing hypertension lends no support to the view that alcohol has an important influence in the production of this type of arterial disease. He has tabulated the histories as to tobacco of 226 men with angioid pain and compared them with 285 men with hypertension, and of 300 other male patients and says that no important influence of tobacco is seen in these figures. In the majority of cases of cardiorenal disease he is convinced that the disease is essentially one of the circulatory system, involving the kidney through its vascular apparatus, and sometimes sparing it entirely. Hypertensive arterial disease must be looked on to-day as the type in which heredity plays the largest rôle. The essayist states that his whole group of private patients gave the cause of death as cardiovascular for both parents or one parent, or one parent and other members of the family in 22 per cent., for one parent or brother or sister in 28 per cent., while 50 per cent. had no cardiovascular heredity at all. He has tabulated all his cases having myocardial insufficiency observed during the period mentioned and finds that one-third of their myocardial failures are associated with hypertension. As another large group of these patients die of apoplexy, hypertensive cardiovascular disease assumes a first place as a cause of circulatory death. Chronic endocarditis stands next, with syphilis of the aorta just behind, each accounting for about one-sixth of the failing hearts. To these may be added the deaths from syphilis of the cerebral arteries and ruptured aneurysms. The clinically primary myocardial insufficiencies, a motley group etiologically, but largely arteriosclerotic, follow with about one-eighth of the blame. Emphysema and its congeners are not far behind, then true bacterial endocarditis, then thyroid intoxication, and various minor causes. The practical conclusions are drawn that reduction of the mortality from circulatory diseases is attainable through the diminution of syphilitic infection and the early and intensive treatment of primary syphilis; the further reduction of preventable infectious diseases; the education of the public to consider "rheumatism" a serious disease, particularly in childhood; the provision of suitable employments for cardiac patients and of convalescent hospitals for the necessarily protracted after care of cases of acute inflammatory disease of the heart and of patients recovering from myocardial insufficiency, and through general hygienic measures including the promotion of temperance. The essayist states that no large reduction of the mortality from circulatory diseases is likely to occur until the problems of the ultimate causes of hypertension and chronic nephritis and the infectious agent of rheumatic fever and its portal of entry have been discovered.

4. Further Experience in the Treatment of Intracranial Hemorrhage in the Newborn.—Robert M. Green recalls that he reported seven cases of intracranial hemorrhage in the newborn in the issue of the *Journal* for April 30, 1913, and discussed the classification of cases, and methods of diagnosis and treatment. Since that time he has observed two further cases of this condition which illustrate those methods. He concludes that intracranial hemorrhage in the newborn may be most conveniently classified clinically under two groups, infratentorial and supratentorial. In the infratentorial type of hemorrhage the symptoms and signs are primarily respiratory in character and are probably dependent on the pressure of accumulating blood about the respiratory center in the medulla. In the supratentorial type of hemorrhage the symptoms and signs are primarily convulsive and are probably dependent on the irritation of the motor area by accumulating blood over the cerebral convexity. In any case of doubt, diagnosis should be confirmed by exploratory lumbar or cranial puncture, or both. In the infratentorial type of hemorrhage repeated lumbar puncture is probably the best palliative treatment and may prove definitely curative. In the supratentorial type of hemorrhage, the best treatment is incision along the coronal suture at one or both lateral angles of the anterior fontanelle followed by brief drainage with rubber tissue. More extensive procedures than these are unnecessary and likely to prove fatal. Early diagnosis and operation within the first two or three days of life are essential for the best results. The prognosis becomes steadily worse as time progresses and clotting takes place.

1. Conservation in Obstetrics.—Edwin B. Cragin questions whether in our enthusiasm over radical obstetric surgery we are neglecting the fundamentals of obstetrics, the routine precautionary measures which may make a resort to radical obstetric surgery unnecessary. He says the consultant still sees cases of puerperal sepsis; of ruptured uteri; of undiagnosed posterior positions of the occiput. He sees cases in which the forceps have been applied too early, cases in which version has been attempted too late. The importance of pelvimetry, uranalysis, and blood pressure readings in the pregnant woman should not be overlooked. He

questions whether the fetal heart is watched as closely as it should be and pleads for the early diagnosis of occipito-posterior positions, and as elements in this diagnosis he emphasizes: (1) The absence of the smooth broad fetal back from the front of the mother's abdomen; (2) the location of the greatest intensity of the fetal heart sounds outside of the line joining the umbilicus and either anterior superior iliac spine; (3) the character of the labor pains, the uterine contractions being often feeble, far apart, and ineffectual. This type of labor is so often found associated with a persistent occipito-posterior position and the diagnosis should at least be suggested and should be either verified or excluded by careful examination. The writer regards cesarean section as a conservative procedure when delivery of a living child through the natural passage is shown to be impossible provided the following conditions are present: 1. Labor of short duration or not begun. 2. Unruptured membranes, or membranes only recently ruptured. 3. No recent vaginal examinations, or only one or two under the strictest asceptic precautions with sterile gloved hands, etc. In the writer's opinion placenta prævia, eclampsia, accidental hemorrhage, etc., furnish an indication for a section only as a rare exception. In certain cases of complete placenta prævia with marked loss of blood and cervix not easily dilatable, a section offers the best prospect to mother and child. The same may be said of certain cases of accidental hemorrhage with complete premature separation of the placenta, but it is the writer's custom to deliver most of these women in some other way, usually after preliminary dilatation with the elastic bag.

3. **Stricture of the Ureter.**—Guy L. Hunner states that he has records of fifty cases of stricture of the ureter since November 1, 1915; in the same period he has treated forty-nine cases of tuberculosis of the kidney and thirty-nine cases of stone in the ureter. He is firmly convinced that the majority of ureter strictures, excluding those of tuberculous and stone origin, should be classified as simple chronic strictures and that they have their origin in an infection carried to the ureter walls from some distant focus, as diseased tonsils, sinuses, or teeth. This conception of stricture postulates that in the majority of cases ureter infiltration is primary and that other urinary tract lesions so often associated with stricture are secondary, such as hydronephrosis, pyelitis, and pyelonephrosis. An analysis of these fifty cases seems to support this view. Another argument for a systemic infection is the preponderance of cases in which the stricture occurs in the broad ligament region where the ureter has its chief blood and lymphatic connections. While the ideal treatment for stricture of the ureter is by dilatation from the vesical approach, and in cases without infection and without much renal disturbance we can look for cure by this method, there are cases in which methods for vesical approach fail and retrograde dilatation may be employed. This method consists in exposing the ureter by an extraperitoneal incision; then making an incision into its dilated portion above the site of the stricture, after which increasing sizes of the French gum elastic bougies or metal sounds are passed until the stricture is dilated to a diameter of from 0.5 to 1 cm. The ureter incision is then closed with catgut and reinforced, if necessary, with silk or linen. The writer has treated eight cases by this retrograde dilatation and the results have been perfect in six, so far as measured by relief of symptoms and ability to catheterize easily from below.

5. **Intradural Nerve Anastomosis in Selected Cases of Poliomyelitic Paralysis.**—Norman Sharpe has carried on a series of experiments upon animals in nerve anastomosis in the spinal canal with the object of caudal root anastomosis in marked cases of paralysis of the lower extremities following poliomyelitis. He reports three cases, but states that it is too soon to give the final results. He says that operation of intradural nerve anastomosis of the cauda equina roots is not more formidable that the frequently performed operation of haminectomy with opening of the dura. The operation is performed in two stages as, for instance, in the first case reported a laminectomy was performed; the spinous processes and laminæ of the twelfth dorsal and the first, second, and third lumbar vertebræ were removed, exposing the dura. The wound was closed with catgut and silk. Two weeks later the wound was reopened and the arachnoid incised. The right twelfth dorsal anterior root was isolated, cut near its passage through the dura, and united by single fine silk suture to the fourth lumbar right anterior root which was severed near the conus. In a similar manner the first and second lumbar right anterior roots were united to the first and second sacral anterior roots respectively.

6. **Contents of Ovarian Cysts.** — J. T. Leary, H. J. Hartz, and Philip B. Hawk have made a study of the toxicity of several varieties of cysts, namely, three multiple proliferating cyst adenomata, one papillary proliferating cyst, one multiple follicular cyst, and one simple cyst of the ovary. They found that the contents of the different cysts were sterile in each case. The cysts examined showed no toxicity, regardless of the nature of their contents. No rise of temperature nor loss in weight was noted in any guinea pig after injection. The animals were killed about twelve weeks after injection, and no lesions could be determined macroscopically. In two cases the physical nature of the contents was mucilaginous in the extreme, having the physical appearance of a mucin substance. That this property was due to the globulin content and not to a mucin substance was shown by the precipitation properties and coagulability of the substance in question accompanies by the lack of viscosity in the resulting filtrates. A slight amount of pseudomucin was obtained in each case, but the trace present could in no way account for the physical characteristics of the contents.

1. **Resuscitation Apparatus.** — Yandell Henderson describes the various forms of resuscitation apparatus now on the market and points out that the mechanical requirements are easily met. The important thing is that the apparatus should be of such simple character as not to impose on the credulity of the ordinary man. All that any apparatus can accomplish is artificial respiration with air enriched with oxygen. The superiority of a mere pump lies in its simplicity. Universal train-

ing in the prone pressure manual method of artificial resuscitation will accomplish more for resuscitation from drowning, electric shock, and asphyxia than is possible by providing any amount of apparatus. Artificial respiration with apparatus is superior to the manual method, in that the apparatus is capable of giving a normal volume of pulmonary ventilation, while the manual method is not. Nevertheless the immediate application of a poor method is far more important than the application of a perfect method after a delay of even five minutes. The knowledge that apparatus is available is liable to result in a neglect of immediate manual treatment in order to have the apparatus brought from a distance. The Resuscitation Commission, after considering the matter in the light of such evidence as is available, concludes that probably ten minutes is the extreme limit of time beyond which restoration is practically impossible. Oxygen inhalation should be used immediately in gas and smoke cases, but the apparatus employed should be such as will allow the oxygen to reach the lungs in efficient concentration. Such apparatus should go with every artificial respiration device. It has been shown that the oxygen concentration obtained by the pulmotor is not very considerable. The writer expresses the opinion that investigation of the use of artificial respiration apparatus in asphyxia neonatorum is needed.

3. **Parenchymatous Disease of the Liver a Cause for Rise in Portal Blood Pressure.**—C. F. Hoover says that in attempting an explanation of ascites in hepatic cirrhosis we must consider the blood pressure and minute volume of flow in the aorta and cava. If the pressure and flow in the aorta and cava are unchanged, then obviously the only hydraulic considerations are those which may affect blood pressure within the portal vein. From clinical experiences in the study of pylephlebitis and portal anastomoses with tributary to the cava, it seems clear that a rise in pressure in the portal vein must precede ascites. Here, however, experiences are encountered which are very disconcerting to this view of ascites if a rise in portal vein pressure is regarded as only an expression of obstruction to portal flow from fibrous tissue formation. Every clinician sees patients with typical alcoholic cirrhosis who have ascites which accumulate very rapidly. The ascitic fluid is drawn off one or more times, and, in spite of the fact that there is no demonstrable change in the hepatic signs, the patient will live for some years without a return of ascites. Two cases are reported. In the first there was the clinical picture of recovery from an acute hepatitis. An acute toxic hepatitis causing an increase in the parenchymatous volume under such conditions would create a higher pressure within the enclosure of Glisson's capsule than would the same degree of parenchymatous enlargement when it occurs within the enclosure of a normal Glisson's capsule with normal and less resistant interstitial tissue. The behavior of the audible hum and palpable thrill in the *caput medusæ* in this case is clear and direct evidence of elevation of portal pressure due to parenchymatous hepatitis in the presence of an old interstitial hepatitis. In the second case there was insufficient direct evidence of an elevation of portal pressure, and this suggested two possible sources of the ascites, namely, either an elevation in portal pressure on account of an acute hepatitis, or merely a hydrops peritonei which happened to be the only collection of extravascular serum because of some modification of the chemistry of the blood. Whatever the cause may be in this second case, the two cases show how important it is to consider the part parenchymatous disease of the liver may play in the diagnosis and treatment of ascites of hepatic origin.

5. **The Use of the Desiccation Method in Ophthalmology, with Special Reference to Epitheliomas of the Lids, Canthi, and Conjunctiva; Report of Cases.**—William L. Clark describes the technique for the application of the desiccation method to eye lesions, and reports on a series of eighty-four cases of localized epitheliomas. The desiccation method consists in the application of heat just sufficient to desiccate but not to carbonize. This heat is best generated by means of a high frequency electric current, which is subject to accurate regulation. The writer concludes that desiccation is a successful treatment for localized basal cell epitheliomas of the lids and canthi, both from a curative and cosmetic standpoint. In advanced epitheliomas of these regions, when sinus or orbit is involved complete success is not certain because of the inaccessibility of the diseased tissue, and is applied for palliative reasons when operation fails or is contraindicated. The results thus far in round cell and melanosarcoma of the lids and conjunctiva have been good, but a sufficient time has not elapsed in any case to determine ultimate results. Success is assured in benign growths of the lids, such as angiomas, warts, moles, xanthoma, and lupus erythematosus. Desiccation may be used to advantage for the treatment of pterygium, granular conjunctiva, and corneal ulcers. Symblepharon usually does not follow desiccation. There is no danger of applying the desiccation treatment to growths on the cornea, as it is under perfect control.

6. **Bismuth Paste in Chronic Suppurative Sinuses and Empyema: Incorrect Technique as a Cause of Failure in Its Application.**—Emil G. Beck believes a discussion of this subject is warranted, because the present war in Europe will result in a tremendous increase in this class of cases. He presents statistics of 527 cases, exclusive of nose and throat cases, from a wide range of sources, and finds an average of 80.64 per cent. of cures. The failures he attributes pincipally to faulty technique. Some of these errors are as follows: The bismuth may not be sufficiently incorporated with the petrolatum and may contain lumps. A little water dropped into the mixture will curdle the solution and make it unsuitable for the treatment. The instruments used are often improvised and not suitable for this form of treatment. Undue force is used in the injection. An incomplete filling of the entire sinus tract is the most common error, which is responsible for more failures than any other cause. The sinuses are injected too frequently by some practitioners. Some patients are allowed to dress their own wounds, reinfection usually following. Physicians at times do not give the paste sufficient opportunity to do the work. The writer confidently states that this treatment has passed its experimental stage, and the results obtained by surgeons all over the world warrant its more general employment. Stereoroentgenograms should be employed to control the treatment and to prevent useless operations. Bismuth poisoning can be avoided and is now of rare occurrence. Should toxic symptoms appear the paste must be removed by washing out the cavity with warm olive oil and injecting sterile oil, which should be allowed to remain for from twelve to twenty-four hours.

7. **Subluxation of the Head of the Radius.**—C. A. Stone reports a case and describes some experiments which he believes throw some light on the production and maintenance of this deformity. From his experiments on twelve arms that were practically free of muscle but on which the ligaments were intact, he concludes that subluxation of the head of the radius can occur while the biceps are contracted, with the forearm flexed and without adduction. It occurs only while the hand is pronated. The line of traction is parallel to

the shaft of the bone. Supination is resisted, because the tense lateral ligament forces the flattened side of the radial head against the anterior edge of the lesser sigmoid articulation and the inner attachment of the annular ligament. Attempts at this motion throw the exposed two-thirds of the long axis of the head against an already tight ligament, making it more tense. Complete pronation is possible, because the short part of the long axis is behind and moves outward against the loose posterior portion of the lateral ligament.

9. Orthopedic Treatment in Hemiplegics of Long Standing. — George R. Elliott and Samuel W. Boorstein say that it has generally been accepted that if a hemiplegic has not improved within a short time he will never improve; but, on the contrary, contractures develop and he becomes a chronic invalid. They report a case which disproves this and indicates that there is no time limit for improvement in hemiplegia. This case further suggests that a patient with hemiplegia should receive proper orthopedic treatments as soon as he regains consciousness. Light massage should be used, and active and passive exercises should be begun early. As soon as the patient is able he should be urged to stand up. Even in old and neglected cases great improvement can be obtained, especially in walking; hence one should work patiently on any hemoplegic who comes under his professional care.

2. Intestinal Disorders Arising from Protozoal Infection.—B. R. G. Russell reports three cases of infection with *Entameba histolytica* s. *tetragena* and one case with an infection of *Lamblia intestinalis*. The former three cases showed nothing unusual. The fourth case, however, failed to respond to two courses of emetine and a chronic dysentery was established. Alternate views have been advanced to explain this phenomenon, the first an anatomical and the second a biological. It is possible to conceive a few amebic cysts locked up in a fragment of more or less dried intestinal content, perhaps lodged in a crypt, where the emetine cannot gain access. The other possibility is after the analogy of certain trypanosomes, easily killed by a particular organic compound of arsenic, which may after exposure to this drug, under conditions not exactly determined, become insusceptible to the action of this very arsenical compound. This insusceptibility or arsenic fastness becomes a character of the trypanosome through subsequent generations. The ameba of dysentery may in like manner become immune to the action of emetine. In the third case the relapse occurred after long treatment with emetine and the conditions for the establishment of an emetine-fast ameba were present. Fortunately, however, the cause of the relapse did not lie in the presence of a permanently emetine-fast ameba. Hence it seems that the whole question why certain cases relapse demands further research. In conclusion the author states that the problem for the clinical pathologist is to recognize the causative organisms in the stools. Accurate measurements must be made of these by a micrometer eyepiece whose value has been reckoned out for the various objectives by means of a ruler slide. For a study of active amebæ from an acute case of dysentery a warm stage is indispensable. In detecting the encysted forms of *E. histolytica* double-strength iodine solution, as recommended by Dr. Wenyon, has proved of great service. The solution is made up similarly to Gram's solution, only double quantities of iodine and potassium iodine are measured out. The writer gives the technique for a further cytological study and the permanent preservation of interesting specimens.

6. Spinal Anesthesia: With Reference to Its Use in the Trendelenburg Position and for the Prevention of Shock.—H. M. Page and Harold Chapple express the opinion that for all ordinary uncomplicated cases inhalation anesthesia as improved at the present day is still the method of choice, but that there remain many cases in which great advantages may be obtained by the use of spinal anesthesia. The operations in which these advantages may be of special importance are those for acute abdominal conditions, especially if septic in nature; any prolonged abdominal procedure likely to be followed by shock; amputations; operations of the bones of the lower limbs, especially when the patient's vitality is lowered by exhaustion, sepsis, or hemorrhage; and certain genitourinary operations. The writer reports seventy cases in which the patient was placed in the Trendelenburg position after the intrathecal injection. He states that he might have reported many more cases in which the patient was put on a slight incline, with the head lower than the body, without any trouble occurring, but he included only those placed in the Trendelenburg position. When this position is used it is better to combine a general anesthetic with the spinal injection, for the small quantity of ether or chloroform mixture required to keep the patient unconscious when there is no reflex disturbance has no necrotic effect on the tissues and practically has very little effect on the after condition of the patient. The administration of nitrous oxide and oxygen for prolonged periods is quite easy, either after a spinal injection or in conjunction with satisfactory local infiltration with novocaine. In twelve cases in this series, however, no general anesthetic was administered. In three cases there was a partial failure, and more or less deep inhalation anesthesia was required. No patient died on the table or before recovery from paralysis. There was no case of surgical shock in the series. In some cases there was a fall in blood pressure without quickening of the pulse rate, remediable by raising the legs to a level with the rest of the inverted body. Harold Chapple adds a note to this article in which he states that he has been using spinal anesthesia during the past four years in operations on the female pelvic organs and is thoroughly in agreement with the author as to the value of this method. He finds it specially indicated in operations in which great surgical shock is anticipated, as in a Wertheim operation for carcinoma of the cervix. By this method of anesthesia this operation can be safely performed, especially if normal saline be at the same time introduced into the axillæ after the method of Arbuthnot Lane. From the surgeon's point of view the great advantage it affords is in the complete relaxation of the abdominal muscles. Novocaine with adrenalin was used in the majority of the cases, the dose varying from 2½ to 3 c.c.

7. Observations on the Treatment of Anaphylaxis.—Albert S. Leyton and Helen G. Leyton record their experiments on the excised rabbit's heart, and believe that anaphylactic phenomena is mainly due to a toxic com-

bination of horse serum and patient's or animal's serum and that it is dangerous chiefly on account of the effect on the central nervous system and the cardiac muscle. These observations led the writers to investigate some possible remedies or prophylactics. The problem was attached by a modification of the serum so as to eliminate the toxic element, or by treatment of the patient, either before or after the onset of symptoms. Efforts to effect a modification of the serum have thus far been attended with little success. Nevertheless, the treatment of anaphylaxis, at least in the guinea pig, is not entirely hopeless, if due preparation is made. Rosenau and Anderson state that untreated guinea-pigs never recover if the anaphylactic condition has proceeded to the convulsive stage. This has also been the experience of the writers but they have found, in addition, that the injection of alcohol or of spirit of camphor has in some cases averted death even after convulsions have begun. Inasmuch as the nervous element is almost certainly involved in anaphylaxis, they have tried certain drugs alone and in combination, acting both centrally and peripherally on the nervous system. The drugs which they have successfully used in averting anaphylaxis in a large percentage of instances are hyoscine, scopolamine, morphine, and atropine. In combination both hyoscine and scopalomine have a distinct influence in preventing anaphylactic shock, but only hyoscine will do so by itself. This the observers atribute to the more central action of the hyoscine. Morphine and atropine by themselves do not possess any noteworthy protective power, but appear to counteract the dangerous properties of hyoscine. In concluding, the writers strongly recommend the use of hyoscine previous to the injection of serum for a second time in any case in which the interval since the previous injection has exceeded one week.

2. Observations on Spirochaeta Eurygyrata, as Found in Human Feces.—H. B. Fantham, in examining the feces of soldiers who had contracted various forms of dysentary or diarrhea in Gallipoli or Flanders, found 23 cases of single infection with spirochetes within three months. He found that the spirochetes were seen to be more numerous in a preparation and to occur more frequently in stools if dark-ground illumination is used. Also if stained smears of stools are made, many more infections will be found, perhaps in as many as 50 per cent. of the cases. The same spirochetes were found in the stools of some apparently healthy persons. The organism, which has pointed ends, measures from three to fifteen microns in length and about 0.25 of a micron in breadth. The so-called spirilla mentioned by some of the earlier workers as occurring occasionally in cholera motions are included under the name *Spirochæta eurygyrata*. The number of coils in a spirocheta is not a specific character but is variable, and is primarily an index of the rate of motion, being also partially dependent upon the rate of thickness of the organism.

3. Perforating and Penetrating Wounds of the Chest with Severe Hemorrhage. — A. Don offers a method of treatment for this class of wounds which he thinks is worthy of trial by surgeons at the front. He says the severer cases almost all die of hemorrhage within the first few hours, and so far there has been little attempt to check this mortality. A study of the mechanism and physics of respiration show that the suction in the pleural cavity is exerted strongly from the commencement of the act of inspiration to that of expiration, and more feebly during the whole expiration. A bleeding point thus has a suction pump applied to its open rent and a clot is prevented from forming. The same process takes place throughout the lung tissue and there is added the elasticity of the lung tissue itself which pulls apart and keeps open any rent. To overcome both the suction and the elastic forces and to allow the lung a complete rest until hemorrhage has been arrested the idea occurred to the writer of making a temporary opening into the pleural cavity, allowing the lung to contract quickly, and, if necessary, washing out the blood clot. In most of the cases of chest wounds, especially from shells, the hemothorax has later become septic and death from empyema has supervened. This infection of the blood clot is almost certain to occur. The risk, then, of causing by operation an infection which would not otherwise occur is almost infinitesimal, and on all grounds this suggestion wisely used in selected cases seems sound. In the only case in which the writer has done this operation great relief was experienced in breathing; there was a marked diminution of pain and, though the hemorrhage could not be said to have been severe, it was still going on and stopped quickly after the operation. The operation may be done under a general or a local anesthetic, and in any of the usual sites for empyema, preferably the mid-axillary line. Percussion localized the hemothorax and a stab is made with a scalpel through the intercostal space, close to the lower rib. Even if the point of the scalpel wounds the lung, which is most unlikely, the consequence is negligible. The knife is then withdrawn and the center piece of a tracheotomy tube put in. If air has not entered it will now do so, with a hissing noise, and the blood will be coughed up. The whole operation does not occupy a minute and the tube may be removed after twenty-four or forty-eight hours. The patient upon whom this operation was performed went to the base hospital on the third day in quite fit condition.

Statistics of Death Due to Childbirth.—Zinke states that during the past fifty years Germany has lost 400,000 women from puerperal causes, while in the United States, during the same period, the loss is estimated at 1,000,000. During the past forty-five years our population has increased by 40,000,000, while in Germany the increase is about one-half this figure. With a like increase in population during the next fifty years, the death rate from puerperal affections remaining unchanged, the mortality will be appalling and the morbidity is computed now at three or four times the mortality. To show how much of this is really preventable, we only have to bear in mind the absence of mortality in well-conducted maternities when all conditions can be controlled.—*Bulletin of the Lying-In Hospital of New York.*

Contraindications to the Karell Diet.—E. H. Goodman states that there are cases which do not respond to this restricted milk diet, in which the latter is no longer recommended. Patients exhibiting symptoms of uremia should not be put on the Karell regimen, since the latter restricts to a minimum the intake of fluids. It has been shown by Senator and others that in a uremic crisis the fluid intake should be greatly augmented for the purpose of flooding from the system the unknown toxic substance or substances believed to be the causative factor in uremia. Wittich states that the Karell cure in two cases of uremia left him absolutely in the lurch, and the patients were made materially worse. The treatment of such individuals should be that well known to all practitioners of medicine, and the Karell regimen has no place whatever in the management of such cases.—*Archives of Internal Medicine.*

Insurance Medicine.

Cooperation of Medical Director and Local Examiner.—Dr. B. L. Jenkins read a paper before the Section on Life Insurance, State Medical Association of Texas, on this subject. In the course of his remarks he pointed out that the duty of the local examiner is not alone to the company: the applicant also has rights to be considered. So accurately have mortality statistics been calculated, correlated and tabulated, that the expectant period of life, at all ages, and under all the varied conditions and environments, has been reduced mathematically to hours. This being true, all or practically all men and women are entitled to life insurance of some form at some rate. To accurately arrive at just what that form and that rate should be, the local examiner should be able, and it should be his purpose, to furnish to the medical director a pen picture, with the perfectness of the artist's brush, not alone the physical finding and measurements resulting from a careful, painstaking, and competent examination, but the habits, environment and life of the applicant. After such a picture has been transmitted to the medical director, and he has carefully reviewed it from its every angle and studied its every phase, as the art critic should, if in any doubt about any point it is his duty, not only to the company but to the examined and the applicant, and it should be his invariable rule and custom, to at once confer with the examined in an effort to gain more complete information. Or if he does not concur in the recommendation of the examiner, he should at once confer with him, giving specific reasons for such non-concurrence.

A local examiner who would not truly paint is unworthy; and the medical director who fails at any time in dealing frankly and freely with his local examiner is a misfit in the position he occupies.—*Texas State Journal of Medicine.*

Diseases of the Circulatory and Hematopoietic Systems in Relation to Obesity.—In a paper on disease in relation to obesity, Dr. F. Parkes Webber said that it was well known that many obese persons had slight edema about the ankles when they were up and had not been recently lying down. In most cases he believed the edema was not a sign of particularly bad prognostic significance. Occasionally, however, it rapidly increased and became associated with shortness of breath on exertion, out of all proportion to the obesity. It then might constitute an early sign of cardiac failure. Especially was this to be feared in persons who had been formerly addicted to excess use of beer and alcoholic drinks, even when by auscultation of the heart no murmur of valvular disease could be discovered. In such cases signs of so-called "myocarditis" might suddenly arise, accompanied by the characteristic "irregular inequality" of auricular fibrillation. In other cases the slight edema in question might be due partly to varicose veins, and it was only the varicose veins that had to be considered in regard to the assurance. Occasionally a plethoric type of obesity might to some extent mask the presence of arteriosclerosis and commencing aneurysm of the aorta. Symptoms such as shortness of breath and thoracic discomfort might at first be wrongly attributed to the obesity, but more exact examination would probably reveal quickly the complicating disease. In very rare cases in pasty, obese individuals, pallor and slight edema might be due to some hematopoietic disorder, or, for instance, to pernicious anemia or to an atypical form of leucemia.—*The Assurance Medical Society of London.*

"Accident"—Anticipated Consequences.—In an action on an accident indemnity policy it appeared that the insured had been out horseback riding, and, coming home, took a cold plunge, as he had frequently done before, the shock of which cause an acute dilatation of his heart for 29 weeks. The insured had been a well and active man, and had no organic trouble with his heart. The plaintiff recovered a verdict and judgment in the trial court, which was reversed on appeal. "It can hardly be asserted," the court said, "that the act of voluntarily entering a bathtub filled with cold water is an accident. If some one had pushed the insured into a tub so filled, or, for that matter, into a pond of cold water, and the results had followed which ensued when he voluntarily committed his body to the water, then the act would have been an accident in the ordinary acceptation of the term. It is not an accident for which an insurance company would be liable if one so insured, while in a state of lively perspiration, stand before an open window, take cold, and die; nor if, by some gross immoderation in eating, acute indigestion be occasioned, and heart failure result; nor yet if in taking a dose of strychnine, aware of its poisonous nature and knowing that in certain sized doses it is a heart stimulant, and not deadly, but mistaking the effect of a given quantity, death ensues. It is urged that heart dilatation is not usually attendant on the taking of a cold bath. When it does occur, it is unexpected, unusual, and unforeseen, and therefore an accident. Undoubtedly an accident, in both its technical and commonly accepted meaning, is an event which occurs without one's foresight or expectation and wholly undesigned; yet it is not true that every unusual, unforeseen, and unexpected event is an accident within the true meaning of the term as used in insurance policies. * * * In this particular instance the weakened heart failed to do its work properly; the sudden contraction of the surface blood vessels must have necessarily and correspondingly increased the blood pressure, thus throwing an additional burden on the heart. It failed to respond to the work of propelling the blood over the body, and acute dilatation occurred. * * * The court is constrained to hold that the result which followed the taking of the bath by the insured was not an accident upon which recovery can be had under the wording of the policy (which insured against bodily injuries effected solely and exclusively by external, violent, and accidental means). A case is cited where recovery was had by reason of a ruptured blood vessel occasioned by the mere lifting one's self naturally out of a chair. It is felt by this court that in such a case, as in the case at bar, such a conclusion would be unduly pressing the construction of the language universally employed in naked accident policies. It would amount to an unfair and unjust enlargement of the company's liability and would convert accident companies into both sick-beneficial and life insurance companies; and, worse than this, the apparent vice of it is that, if countenanced, it would inevitably result in the necessity of requiring constantly increasing premiums from the vast multitude of the laboring classes as well as people of moderate means who chiefly buy this character of insurance."—New Amsterdam Casualty Co. v. Johnson, 91 Ohio St. Rep. 155, 110 N. E. 475.

Book Reviews.

El Problema de la Meningitis. Por el Dr. César Juarros, Medico primero de Sanidad Militar, Professor de Psiquiatria del Instituto español criminológico, Jefe de la Consulta de enfermedades nerviosas del tercer Dispensario de la Cruz Roja; Professor agregado del Instituto de Medicina legal. Price, 4 pesetas. Madrid: Hijos de Reus, 1915.

Those who are interested in the subject of meningitis and who are able to read the Spanish language will find this volume a valuable digest of the latest knowledge of the various affections of the meninges. This knowledge has grown rapidly during the past few years, chiefly through the contributions of French clinicians. The author has made a thorough survey of the literature of meningitis and has succeeded in presenting an epitome of it in a form that is no less interesting than instructive. Chapter I deals with lumbar puncture and ventricular puncture; Chapter II, with the symptomatology of meningitis; Chapters III and IV with laboratory data; Chapter V, with tuberculous meningitis; Chapter VI, with meningococcus meningitis, and Chapter VII, with syphilitic meningitis, and the types of meningitis caused by the pneumococcus, the typhoid and influenza bacilli, the gonococcus, the streptococcus and other microorganisms, and the meningitis associated with parotitis. In Chapter VIII there is discussed the so-called toxic meningitis, including the uremic and serous, and those caused by salvarsan and carbon monoxide. The types of meningitis of difficult classification are described in Chapter IX: these types are the otitic and traumatic meningitides, and the meningitis associated with zona, insolation, Pott's disease, cysticercus, and trichinosis. The meningeal reactions are dealt with in Chapter X. The author believes that the term meningism should be discarded, for in all cases in which the meningeal syndrome is present he believes there are distinct pathological changes in the meninges. Chapter XI deals with the localized types of meningitis: the spinal and the cerebral. A most important topic constitutes the subject-matter of the following chapter, namely, the meningeal hemorrhages, the various types of which may be differentiated by an examination of the cerebrospinal fluid. The treatment of meningitis is exhaustively discussed in Chapters XIII and XIV. Various important points are summarized in Chapter XV, and Chapter XVI deals with meningococcus meningitis as it has been observed in Spain. An idea of the thorough manner in which the author has elaborated his theme may be gleaned by noting the subdivisions of the type of meningococcus meningitis as observed in the newborn. The following varieties are mentioned: the typical, the abortive, the prolonged, the fulminant, the hypersthenic, the posterior basilar, the tetanic, the type accompanied by paralysis of the neck muscles, and the uremic. The book on the whole is one of the most important contributions that have been made within recent years to the literature of meningitis, a contribution out of all proportion to the modest size of the volume.

A Handbook of Colloid Chemistry. The recognition of colloids, the theory of colloids, and their general physicochemical properties. By Dr. Wolfgang Ostwald, privatdozent in the University of Leipzig. First English edition translated from the third German edition by Dr. Martin H. Fischer, professor of physiology in the University of Cincinnati, with the assistance of Ralph E. Oesper, Ph.D., instructor in chemistry, New York University, and Louis Berman, M.D., staff physician, Mount Sinai Hospital, New York. Price, $3.00 net. Philadelphia: P. Blakiston's Son & Co.

The first part of Wolfgang Ostwald's textbook on colloidal chemistry has passed through a number of editions in German, and has been generally accepted as a standard presentation of the physics and chemistry of bodies whose surfaces are very large in proportion to their other dimensions. Unfortunately, the second part has never appeared, and it is to be regretted that the translators of the present volume have not deleted references to this proposed continuation, as on pages 39 and 82. In some instances, also, as at the bottom of page 28 and the end of the second paragraph on page 158, the statement is made that a matter will be discussed in detail later; as the details are not to be found in this volume in connection with some of these references, it is to be presumed that they refer to the unpublished volume. The only other errors noted are the use of "exterpolations" for "extrapolations" on page 58, and the inclusion on page 98 without criticism of some highly improbable statements on the increased radioactivity of substances in colloidal form. If there is anything we know about radioactive substances it is that they are not influenced in their energy emission by any physical or chemical means at our disposal. These minor defects, however, in no way diminish our obligations to Dr. Fischer and his collaborators in the production of a very admirable translation of an extremely valuable book. While the results of the study of colloidal chemistry are important in commercial life, applying to many processes of manufacture, especially dyeing, they are also fundamental in many biological reactions, as substances of large molecular weight, such as proteins, soaps, and some of the carbohydrates of the body are subject to mechanical laws which govern colloidal suspensions. It is generally held, also, that the reactions between the various antibodies and antigens are best explained by supposing that their condition is colloidal. While the details are highly technical, the physician will find much of interest in this volume, for there is no question that in the future a much fuller use of the methods of analysis here presented will be made in physiology and pathology. At the present time the science is not advanced sufficiently far to result in important practical applications to medicine, though general biology has greatly benefited.

Principles and Practice of Physical Diagnosis. By John C. DaCosta, Jr., M.D., Assistant Professor of Medicine, Jefferson Medical College, Philadelphia. Third edition, thoroughly revised. With 243 original illustrations. Price, $3.50. Philadelphia and London: W. B. Saunders Company, 1915.

Though progress in diagnosis has of recent years been effected rather through developments in laboratory procedures than by innovations in the methods of immediate examination of the patient, still in this field, as in all other departments of medicine, there have been advances of some importance. Accordingly there has been no lack of new material to incorporate in the third edition of this most excellent treatise on physical diagnosis. Electrocardiography naturally is one of the most important of the added subjects and is discussed clearly and explicitly, with its practical applications indicated as far as present knowledge permits. Radiography in gastroenterological diagnosis and also in the study of thoracic disorders receives much new space, as well as the recent lore in regard to cardiac irregularities, auricular flutter, fibrillation, etc. Especial attention must be called to the very numerous and unusually useful illustrations which form so vital a part of any book on physical diagnosis and are particularly well chosen in the present admirable volume.

A Treatise on Medical Practice Based on the Principles and Therapeutic Applications of the Physical Modes and Methods of Treatment. By Otto Juettner, A.M., Sc.M., Ph.D., M.D. Price, $5. New York: A. L. Chatterton Co., 1916.

This is a one-man cyclopedia, the matter being arranged alphabetically. From the numerous affiliations of the author, which are too many to reproduce, we gather that he is well qualified to write on the physical and dietetic treatment of disease. But it is strange to find a reference work comprising such subjects as radiography, electrotherapeutics, Swedish movements, etc., without a single illustration! And this, too, in an era when pictures seem to count for more than text.

Manual Practico de Anestesia (General, Local, Regional y Raquidea), por J. Blumfeld, M.D., Cantab, Primer, Anestesiador del Hospital de San Jorge y Profesor de Anestesia del de Santa Maria en Londres. Traducido directamente de la tercera edicion inglesa y completado con un apéndice por D. Julio Optega, Doctor on Medicina. Prólogo del Dr. D. Juan Bravo Coronado Cirujano de numero de la Beneficencia provincial. Price, 3.50 pesetas. Madrid: Hijos de Reus, 1914.

This work is a translation of the third edition (1912) of Blumfeld's "Anesthetics: A Practical Handbook." The translator has added some text on somnoform and liquor somniferus, which substances appear to be in favor in Spanish and Portuguese speaking countries; also on intravenous and conduction anesthesia. A brief critical summary completes the text.

Society Reports.

MEDICAL SOCIETY OF THE STATE OF NEW JERSEY.

One Hundred and Fiftieth Annual Meeting, Held in Asbury Park, June 20, 21 and 22, 1916.

(Special Report to the MEDICAL RECORD.)

Tuesday, June 20—First Day.

THE PRESIDENT, DR. WILLIAM J. CHANDLER OF SOUTH ORANGE IN THE CHAIR.

House of Delegates.—After the call to order by the President, the presentation of credentials by the delegates, and the adoption of the minutes of the last meeting the following reports were presented.

Report of the Recording Secretary.—Dr. THOMAS N. GRAY of South Orange presented this report, which showed that the membership of the Society on June 1, 1915, was 1,649; that there had been a gain of 187 new members; that after deducting the losses occasioned by death, resignation, and failure to pay dues there was a net gain of 51 members, making the membership at the present time 1,700.

Report of Committee on Publication.—Dr. AUGUST A. STRASSER of Arlington reported for this committee. He stated that for the first time in the history of the State Journal it had shown a profit, a little over seven dollars. This was small indeed, but it held much that was promising for the future. They had found that co-operation with the Advertising Bureau of the American Medical Association had been greatly to their advantage. Their advertisements were all ethical and they recommended that when members could conveniently do so they patronize those who had contributed by their advertisements to the financial success of the Journal. It should be remembered that medical defense in malpractice suits was only given to subscribers to the Journal. The July, August, and September numbers of the Journal would be of special value and would constitute a memorial of the One Hunderd and Fiftieth Anniversary of the Society.

Report of Committee on Legislation.—Dr. HENRY B. COSTILL of Trenton presented this report in which he cited the principal measures which had come before the Legislature during its past session which affected the welfare of the medical profession. Among these were bills aiming to relieve the physician of his obligation to guard professional secrets on the witness stand, and bills legalizing the practice of osteopathy and chiropractique. All of these bills were defeated, the osteopathy bill not before it had passed the lower House and the chiropractique bill not until after it had passed both Houses of the Legislature. This committee urged stronger co-operation on the part of the county societies in the efforts to influence legislation affecting the practice of medicine and public health. In view of the amount of time that was required of those who attended hearings at Trenton it was recommended that a tax of one dollar be levied on every member of the Society to defray the expenses of such men as should be chosen to assist the Legislative Committee of the State Society. It was pointed out that the members of the county societies frequently could exert greater influence on the assemblymen and representatives from their localities than could be brought to bear at Trenton by physicians who were unknown to the assemblymen.

A lengthy discussion on these recommendations emphasized the need of sending men before the State Legislature who were familiar with the problems of the medical profession and who were able to present their viewpoint in a way that would carry conviction. The various cults when they wished to secure the passage of legislation favorable to their interests hired the best legal talent available to present their side and had their supporters flood the mails of assemblymen with letters urging the special measure in which they were interested. It was further pointed out that the family physician of a representative was in a position in which he could do a great deal to enlighten that representative and to bring a direct influence to bear on him; it was his duty to exert this influence. After a lengthy discussion as to the advisability of levying an additional tax of a dollar on each member this question was referred to the Business Committee for further consideration.

Resolutions on Stream Pollution.—Dr. LUTHER M. HALSEY of Williamstown stated that the New Jersey State Department of Health was in session and has passed resolutions opposing the discharge of partially purified sewage into the streams of the State and that they would like to have the State Medical Society endorse these resolutions. The resolutions were endorsed by the Society, but it was pointed out that it should have specified more definitely what was meant by partially purified sewage.

Report of the Treasurer.—Dr. ARCHIBALD MERCER of Newark presented this report, which showed the finances of the Society in thriving condition, there having been $5,194 in the treasury on January 1, 1916.

Report of Board of Trustees.—Dr. JOHN M. WARD of Trenton presented this report, in which satisfaction was expressed with the reports of the officers. It was announced that Dr. Edward J. Ill of Newark had been appointed Chairman of the Board of Trustees and Dr. David C. English of New Brunswick had been re-elected Editor of the Journal.

Report of Special Committees.—Committee on Standardization of Hospitals.—Dr. JOHN C. MCCOY of Patterson made this report. He stated that this committee had inspected forty-three hospitals in the State of New Jersey. The importance of standardizing hospitals was evident since the Board of Medical Examiners of New Jersey required that every applicant for a license to practice medicine should have had one year's hospital experience. In this inspection notice had been taken of the physical plans of hospitals, the conditions with reference to financial management, and the provisions for the care of patients. A great deal of information had been collected and analyzed. The facts which had most impressed the committee were the lack of uniformity in the essentials of hospital management and the failure in some instances to achieve the main object of the hospitals, the proper care of the patient. The hospital must be judged by its results and many hospitals failed to give value received for the money expended. The statistics of some of the hospitals gave very little information as to the efficiency of hospital management. There was a lack of attention in the medical department to historical data, and the management had failed to require such data. The committee suggested that a blank form should be incorporated and that the use of such forms should be made compulsory and introduced into the annual reports of all hospitals. The reports from the hospitals should give the wages of all employees, the average stay in the hospital of the patients, the average cost of maintenance of each patient, etc. The State Board of Medical Examiners had given their hearty co-operation in this investigation and had assisted the committee in deciding upon the minimum requirements in the way of equipment for a pathological laboratory. It was found that a hospital laboratory could be equipped at a cost of $600. The detail of such equipment was given in the full report. The results of this effort at hospital standardization had been given to the American Medical Association. This organization had congratulated them on their work and had stated that this was the first instance in which a hospital standard had been submitted to them. It was difficult to make the standard as high as it should be at the present time, but with a minimum standard once established the standard could gradually be raised. This investigation had also shown them that co-operation between the boards of managers of the different hospitals, if it could be brought about, would offer great economic advantages.

Report of the Judicial Council.—Dr. WILLIAM H. ISZARD of Camden presented this report, in which he emphasized the advantages of medical defense and cited a number of cases which had come up during the past year. In several instances the mere fact that the physician against whom action was brought applied for medical defense was sufficient to bring about a withdrawal of the case.

Report of Committee on Economics.—Owing to the death of the chairman of this committee, Dr. Frank N. Gray of Jersey City, one of the members of the committee presented this report. This report stated that it had been conservatively estimated that the illegal practice of medicine cost the people of the State of New Jersey $7,000,000 annually. It had also been estimated that the illegal practice of medicine cost the people of the United States $400,000,000 annually. There was a book published called "The Druggist's Manual," which contained 2,800 prescriptions, of which 1,400 were so-called "cures." With such a state of affairs it was not to be wondered at that the members of the Society would not stand a further tax of one dollar a year.

Report of Committee on Tuberculosis in Childhood.—Dr. GORDON K. DICKINSON of Jersey City presented this report, which embodied the results of the work of a special committee appointed by the Society to investigate the prevalence of tuberculosis in children and to make suggestions. This report emphasized the well-known fact that infection with tuberculosis in childhood was responsible for the large majority of cases of tuberculosis in adults. Future generations would wonder why, when we possessed this information, we had not acted upon it in such a way as to control this disease. This committee recommended that resolutions be passed to the effect that the State Board of Health be called upon to look to the sanitary condition of the schools in regard to the prevention of tuberculosis; this meant open air, not open window, schools, for tuberculous and anemic children. It was further recommended that the influence of this Society be brought to bear on legislative bodies in order that sanatoria or preventoria might be established for the care of tuberculous children. This action was urged as a fitting memorial of the One Hundred and Fiftieth Anniversary of the Society.

Election of Honorary Members.—The following were elected honorary members of the Medical Society of the State of New Jersey: Dr. J. K. Mills of Philadelphia, Dr. Hugh Cabot of Boston, Dr. George W. Crile of Cleveland, and Dr. James B. Deaver of Philadelphia.

Report of Publicity Committee.—Dr. JAMES HUNTER, Jr., of Westville made this report. He stated that inasmuch as the general public were showing great interest in matters pertaining to public health and inasmuch as the newspapers published articles on these subjects which were incorrect and misleading, they had selected 125 papers and had sought to co-operate with the editors in the publication of suitable articles. Seven such articles had been prepared and published without the names of their authors in a considerable number of newspapers. Later inquiry was made as to how they had been received; the replies received showed that the newspapers would be glad to continue to print articles of this kind provided they were short, were on subjects of general interest, and preferably, if possible, had some local coloring.

Report of Business Committee.—Dr. THERON T. SUTPHEN of Newark reported for this committee, to which the reports had been referred for consideration. The committee approved the recommendations made by the Committee on Tuberculosis in Childhood. The recommendations of the Legislative Committee were referred to the house for decisive action. After long discussion it was decided to leave the matter of paying the expenses of delegates sent to appear before the Legislature to the county societies. The resolutions presented by the Women's Christian Temperance Union asking that the Society endorse resolutions calling attention to the harmful effects of alcoholic beverages and to the growing disuse of alcohol as a therapeutic remedy by members of the medical profession. This resolution was then referred to the Committee on Public Health for further consideration. With reference to the subject of prize essays, the committee recommended that the Trustees be empowered hereafter to choose a subject, since no essay had been presented under the present way of allowing anyone to choose his own subject. The House of Delegates had been asked to endorse a resolution recommending the reporting of venereal diseases. In the opinion of the committee this was a matter that should be left to boards of health under present conditions.

The House of Delegates acted in accordance with the suggestions of the Business Committee on these matters.

GENERAL SESSIONS.

Tuesday, June 20—First Day

Invocation.—Rev. A. E. BALLARD of Ocean Grove made this invocation.

Address of Welcome.—Mayor C. E. F. HETRICK made a brief address welcoming the Society to Asbury Park.

Indications for Surgery.—Dr. EDWARD J. ILL of Newark made this address. He said that a foreign surgeon visiting this country had expressed his admiration of the technical qualifications of American surgeons, but regretted that about 50 per cent. of the cases were operated upon without indications. If the object of surgery was to get rid of a diseased organ, or organs, or tissues which gave the patient no inconvenience, if it was for the purpose of getting a rare or interesting specimen, if it was for the purpose of doing an operation, if it was for an imaginary danger to the patient, or, though one hesitated to say it, if it was for the exaction of a fee, it should not be done. Operation should be considered only when it was necessary to save the patient from a real or impending danger or to restore him to health, that was, to remove certain symptoms which incapacitated him from enjoying life and which interfered with his usefulness as a member of society. In the former instance the indication was absolute; in the latter the choice should be left to the patient. Indications for operations must never be based on laboratory or *x*-ray findings, though these might be of incalculable value as corroborative evidence. These were no longer the days when one said the patient had recovered from the operation; the question now was "Will he be well and free from symptoms?" With a good surgeon at hand it might be well to err on the safe side and operate; with a poor surgeon it was better to take one's chances with nature. Among the diseases calling for prompt surgical interference were perforation of the intestinal, biliary, urinary tract, or intestinal obstruction. The lower down in the intestinal tract the perforation had taken place the more urgent the indication for operation. Nowhere was this more forcibly illustrated than in cases of intussusception in children. No condition of the kidney except fracture or wound called for immediate attention. Other operations on the kidney should be done only after careful estimation of the functional capacity of the kidney by laboratory methods. Deliberate and time taking consideration should precede all stomach, intestinal, and intra-pelvic operations. The essayist protested against the removal of ovaries containing small cysts due to simple thickening of the albugenia or simple adherent or displaced ovaries. All ovarian neoplasms, however, he believed should be removed. Fibroids of the uterus should be removed only for good and sufficient reasons. In over five hundred operations on fibroids he had never seen an instance of malignant degeneration. Acute simple inflammatory or suppurating diseases of the genital tract rarely needed operation. Cesarean section in many instances of abnormal labor had become the least mutilating and the safest of any obstetrical operation. Labor should never be induced before term for the convenience of the patient, the nurse, or the doctor, but only with all the indications and care of a major operation.

Education of the Nurse.—Dr. GORDON K. DICKINSON of Jersey City presented this paper, in which he stated that an increasing number of well-educated young women had entered the profession of nursing with the result that they had idealized the profession, and as a consequence the nursing profession had exerted an influence on hospitals, allied institutions, and legislatures. Laws had been enacted which affected more or less severely the source from which the nurses were acquired. The work of the nurse in general practice was uncertain, irregular, and sometimes very tiring; this together with the high standard of educational requirement afforded the reason for the small number of girls applying to the training schools. An investigation of twenty-two hospital superintendents, seventeen physicians, and seven nurses showed that the large majority felt that the present demands were not exorbitant, that they should be lived up to, and that the present condition did not warrant change. The time had come for a reconsideration of the whole matter. The question arose as to whether it was fair to the applicant who came to the hospital to be trained to use her as much as she was used for the convenience of the institution and to neglect so largely the bedside training. Too often the nurse's training was left to a subordinate nurse, while those paid for that purpose were seldom seen at the bedside. Gross errors were too often controlled by severe discipline instead of being remedied by precept and example. The essayist, in closing, requested that the Society should appoint a committee to investigate the methods of instruction and training in the training schools of the State, the principles underlying hospital training schools, to consult with the nurses who had graduated and those who were in training, and to report at the next annual meeting as to whether the present method of training nurses was the most satisfactory, or whether it would not be more wise to take the young woman from the grammar school, give her two years intensive training at the bedside, supplemented by book instruction, and then with hospitals standardized, to inquire whether a diploma from such an institution would not be sufficient without compelling a second examination at Trenton. It must be remembered that nurses were needed for homes, and for physicians, and surgeons in their general practice, and that preparation for

higher positions might be left to a post-graduate course.

Dr. Edward J. Ill of Newark said he agreed with much that Dr. Dickinson had said. The average life of active service for a nurse was about ten years. If for this ten years she spent three years of preparation in a hospital one need not look long for the cause of the diminishing supply. A nurse could learn all she need know in two years. An instance had come to his attention in one institution where ten lectures were given the nurses on the care of special accidents and eight on scarlet fever. Dr. Ill thought he could tell a nurse all she would need to know about scarlet fever in fifteen minutes.

President's Address.—Dr. William J. Chandler of South Orange delivered this address in which he reviewed the history of the Medical Society of the State of New Jersey. He said, in part, that compared with the zone of time since the crust of this sphere began to harden or from the earliest signs of animal life, one hundred and fifty years seemed like a mere point in the cycle of time, but to us, living from day to day and from year to year, it seemed quite venerable and in this latter conception they had met to celebrate the sesquicentennial of the Medical Society of the State of New Jersey, the oldest medical society in this country. Conditions of life in 1776, when New Jersey was a province in the colonial possession of Great Britain, were quite different from what they were to-day. The geographical boundaries of New Jersey were at that time coterminous with those of to-day. The early settlers settled along the Hudson and Delaware rivers while between these streams lay dense forests of the oak and cypress so that communication between East Jersey and West Jersey was difficult. There were also essential differences in the characteristics of the people. In the east the doctrine of John Calvin prevailed; in the west the Quakers largely predominated. In those days it took more days to make the journey from Philadelphia to New York than it took hours at the present time. The physician of 1776 relied upon his horse and saddle and took not the road but the trail through the forest, fording rivers and streams, and thus travel was only possible during daylight. Danger beset him from bandits, horse thieves, and Indians. The country was overrun with itinerant doctors, mountebanks, fakirs, natural bonesetters, etc. French and English military establishments brought with them educated physicians, and young men of this country either studied with them or went abroad to receive academic or medical training. Many clergymen took medical courses so that they could minister to the body as well as the spiritual needs of the people. The first president of the society was the Rev. Robert McKean of Amboy. He came to this country as a missionary from the Society for the Propagation of the Gospel in Foreign Parts. On his tombstone was inscribed the following: "An unshaken friend, an agreeable companion, a rational divine, a skillful physician, and in every relation of life an honest man." A number of physicians devised a plan for bringing together all the physicians of the province into a society. An advertisement asking them to assemble was placed in the New York *Mercury* calling the meeting for June 27, 1766, in New Brunswick. One of the early and important matters that came before the society was the arrangement of a suitable fee bill for medical and surgical services. Those fees were small in comparison with the fees of the present day, but it was to be remembered money had a greater purchasing power at that time and the doctor furnished medicine and blisters, cups, bleeding, enemata, etc., for all of which he charged extra. The fee for an ordinary visit was one shilling sixpence, and about one shilling a mile for mileage; above fifteen miles it was one shilling sixpence per mile, and above twenty-five miles two shillings. Consultations were fifteen shillings; phlebotomy, one and sixpence; extracting a tooth, one and sixpence; amputating an arm, three pounds; delivery in natural labor, one pound and a half. In conformity with the provisions of the constitution local or "inferior" societies were at once established which were to meet every two months and were to report their proceedings to the General Society at its semiannual meetings. The second meeting of the society was held in Elizabethtown, November 4, 1766. At this meeting Dr. Kean reported a recipe given to him by Dr. Ayres of Newport, R. I., of which the main ingredient was powdered glass. In order to be effective this was to be administered in quantities sufficient to cause violent pain in the stomach and contractions of the extremities. After discussing this remedy the consensus of opinion was that they could not rely too much on this new remedy until they knew something more about it. It was not to be expected that a society having as its object "the advancement of medical science, the elevation of professional character, and the rendering of efficient service to mankind" could be established in a community full of professional jealousies and overrun with irregular practitioners without arousing antagonism. Considerable opposition was encountered and the society finally published its legal instruments in the lay papers and explained its purposes. The fee bill was a constant bone of contention and it was years before one was evolved satisfactory to the members of the society. At the third meeting of the society the subject of medical education was taken up. The society agreed that for the advantage of youth and the honor of the art of medicine no man should be taken as an apprentice who was not competent in Latin and did not have some knowledge of Greek, and no man could take less than four years preparation as an apprentice and one year in some school of medicine in this country or abroad. This work of raising the standard of medical education had been going on ever since and allied with it had been the labor of endeavoring to suppress quackery and all forms of irregular practice. This work would be continued until the laws of New Jersey were inferior to none and applied alike to every practitioner of medicine in this State with justice and equality. The meetings of the society were interrupted during the Revolutionary War, not enough members having been left in their homes to hold a meeting. They gave their services and their lives freely for their country at that time. Meetings were convened in 1781 and in 1783 application was made for a charter of incorporation or such other act as might seem proper to regulate and restrain the practice of medicine and surgery in the State. There seemed to have been some difficulty in getting what they wanted for the charter was not issued until 1793, fifty-two names appearing as incorporators. This charter expired by limitations in 1815. The new charter obtained in 1816 provided for the establishment of a district society in every county and placed the control of the State society under the control of fifteen managers. This arrangement was not satisfactory and in 1818 a supplement was passed making the State society to be composed of four delegates from each of the district societies. The officers of the State society were ex-officio members and the ex-presidents were ranked as fellows and given the rights and privileges of delegated members. The society was conducted on practically the same basis to-day. The American Medical Association found practically nothing to change in the charter and only a few changes in the phrasing of the constitution and by-laws of the society in order to make them conform to their models for State societies. In 1820 the society established a standing committee which did the work of the present committee on scientific work, the judicial council, the committee on publication, and a large part of the work assigned to the board of trustees. The power of examining candidates for medical practice and the conferring of the degree of doctor of medicine was given to the society in 1816. For many years candidates were examined and licensed to practice medicine by the society. This power as still vested in the society through the State Board of Medical Examiners did the work. Some of the examination papers were still available and showed that certain applicants even in those days did not come up to the standard set. Of this the following was an example: *Question*—"What do you mean by an hour-glass contraction?" Graduate, embarrassed and slow in answering, so the examiner asked: "What would you do in a case of hour-glass contraction?" *Answer*—"I would pass a wire." The following was another example: *Question*—"What causes the secretion from the bronchial tubes?" Embarrassed student did not answer. *Question*—"What do you mean by expectoration?" *Answer*—"I can't exactly tell." *Question*—"What would you prescribe as an expectotant?" *Answer*—"James' expectorant; it always works well." *Question*—"What are the constituents of James' expectorant?" *Answer*—"I do not know; he won't tell." These applicants were not granted a degree. Of the recent changes in the constitution and by-laws of the society two were worthy of passing attention, the establishment of permanent delegates and the enrollment of all active members of county societies as associate delegates of the State society. This plan had worked greatly to the advantage of both the State and the county societies. Dr. Chandler said he regretted that time would not permit him to review all the activities

which the society had engaged in for the benefit of the medical profession and for the state at large, such as the institution of insane asylums, founding a relief fund for physicians, prize essays, the *State Journal*, etc.

Oration in Surgery.—Professor JOHN G. CLARKE of Philadelphia delivered this address which he prefaced with a quotation from Samuel Sharpe's treatise on "The Operations of Surgery," published in 1758. He said with reference to the removal of the breast for cancer: "The success of the operation is exceedingly precarious from the great disposition there is in the constitution after an amputation to form a new cancer in the wound, or in some other part of the body. When a scirrhus had admitted a long relay before operation the patient seems to have a better prospect of cure without danger of relapse than when it has increased very fast and with acute pain." When it was realized that it had been one hundred and fifty years since these lines had been printed and took into consideration the widespread skepticism as to the benefits accruing from the surgical extirpation of cancerous growths among many physicians and laymen, one realized most vividly that small progress had been made in the great majority of cases. Little was known of the exact etiology of cancer. Nothing thus far had been accomplished in preventing it and each decade witnessed a steady increase. Each year the number of deaths from cancer in the United States approximated 75,000 and in the civilized world 500,000. All we had to pin our hope on at the present time was the motto of the American Society for the Prevention of Cancer, "In the early recognition and treatment of cancer lies the only hope of cure." The layman must be taught that cancerous growths in no part of the body were painful in the earlier stages and therefore a lump in the breast or abdomen, a small ulcer on the tip of the tongue, or cheek, or on the cervix, was the one condition which should have immediate attention on the part of a competent physician. Any ulcer that did not heal had cancer potentialities. Usually when the patient was stricken with cancer of so advanced degree that there was persistent pain, and when emaciation and a bad sallow color were present, she had passed the possibility of cure. Two fallacies of former years had been cast into the waste basket; first, that cancer was a general blood disease, and second, that it was of hereditary origin. Agnew, in what proved to be his valedictory address (for he died a few months later) given before the speaker's class of the University of Pennsylvania twenty-five years ago, said he could not count one single cure following the removal of the breast in his many years of surgical practice. Since that time methods had so far improved that skillful surgeons of the present era confidently count 30 to 50 per cent. of permanent cures from thorough removal of the disease by radical operation. So long as the theories of former days were held the surgeon could soothe his feelings of professional inadequacy by the theory of incurability. That day had passed and soon the laity would hold the physician to as strict accountability who allowed a patient to drift beyond the safety zone in cancer as they did now when the agonizing pain of appendicitis was falsely diagnosed as acute indigestion or ptomaine poisoning. The essayist stated that in his twenty years' experience he had found nothing to convince him that cancer had an hereditary tendency. A study of all the combined statistics showed that cancer was a disease of middle life, occurring between forty and fifty years of age, and therefore women in the critical period of their lives should be especially alert to bring to the attention of their physicians any decided change in the way of excess. Childs of England had well pointed out the danger signals of cancer. (1) A small lump or thickening of any kind in a woman over thirty-five years of age was a starting point of cancer in 90 per cent. of the cases and the finding of a lump in the breast should be followed by its immediate removal. (2) The danger signal in cancer of the uterus was irregular bleeding, especially after the menopause. (3) The danger signal in cancer of the lip, mouth, or tongue, or skin was a wart or sore that would not heal. (4) In cancer of the stomach and intestines the danger signal was not so apparent; obstinate, persistent diarrhea, vomiting or the passage of blood were danger signals that should be heeded at once. In speaking of cancer of the uterus, Dr. Clarke said that in less than two years he had treated forty-nine cases of inoperable cancer of the uterus with radium and during the same period only twelve cases had been considered as within the radical operative limit. During the preceding ten years about sixty radical operations were performed. Although radical operation had given the best ultimate statistics the primary death rate was unavoidably high and serious operative sequelæ occurred. The essayist said they had abandoned extensive glandular dissections because they added to the hazards and did not increase the permanent cures. There was no middle road in cancer of the cervix; the surgeon had better perform a simple vaginal hysterectomy or a high amputation of the cervix with extensive cauterization than to attempt the radical operation if he was not prepared to execute details. If the growth had invaded the parametrium to a point beyond the outer limits of the ureters or if it had found lodgment in the iliac glands the case must, with rare exceptions, be regarded as hopeless so far as surgical extirpation was concerned. In cancer confined to the fundus, recurrence did not take place in more than 50 per cent. of the cases while in cancer of the cervix in only about 30 per cent. of the cases was there no recurrence. The crux of the matter was that surgery should be attempted only in clearly operable cases, leaving the large remainder to secure relief from therapeutic efforts. Radium offered the most hopeful outlook of any remedy thus far presented in the palliative and even the curative treatment of the borderline and inoperable cases. In the gynecological clinic of the University of Pennsylvania during the past two years forty-four cases of carcinoma of the uterus, vagina, and urethra had been treated. These cases were practically all classed as inoperable. From 85 to 100 grams of radium were applied in a platinum capsule shielded by rubber for twenty-four hours; this was repeated at the end of six weeks. The results of too intensive treatment with radium had in some instances been even worse than the disease itself. In this series, with the exceptiion of two cases, there had been no disagreeable effects. They had adhered to the rule never to attempt to operate in any case that had been healed by radium. Radium as shown by this series of cases was by no means a universal panacea for cancer, even when the growth was strictly localized. In operative cases the average stay in the hospital was three weeks, while for the application of radium not more than three days was required. Dr. Clarke discussed the Percy method of treating cancer of the cervix and expressed the opinion that the results fell far short of those obtained by the use of radium. Removal of the uterus in cases of cancer of the fundus had yielded such good results that taking chances with radium was not justified in these cases. His attitude toward cervical cancer was just the opposite. In the borderline cases of cancer of the cervix they employed radium. Dr. Clarke illustrated his paper by lantern slides.

(*To be concluded.*)

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

Stated Meeting, Held Wednesday, April 5, 1916.

DR. J. WILLIAM TAYLOR, VICE-PRESIDENT, IN THE CHAIR.

DR. A. C. ABBOTT read a Memoir of the late Surgeon-General Sternberg.

A New "Muscle Substitution" Operation for Congenital Palpebral Ptosis.—Dr. JOHN B. ROBERTS presented this contribution from the Surgical Laboratory of the Philadelphia Polyclinic. In November, 1914, a three-year-old girl had been sent to him by Dr. H. A. Stout of Wenonah, N. J., for operative treatment of very marked double ptosis and a moderate degree of epicanthus of both eyes. The child had been taken previously to an ophthalmic hospital but no operation had been performed. Because of the generally unsatisfactory results in operation for ptosis Dr. Roberts devised an operation which he had suggested in 1912 based on the myoplastic methods used in traumatic and orthopedic muscular deficiencies. Believing it best, however, to try at first one of the already recognized ophthalmic procedures the Tansley method was followed in an operation upon both eyes. Following this the child could uncover the eyeball so that in the right eye about one-half the cornea was visible. The left eye was not so satisfactory in result, although the lid could be lifted somewhat better than before the operation. In March of this year the child was returned for further treatment. It was determined upon the present occasion to lessen the epicanthus by an arrowhead-shaped excision of skin and superficial fascia by Berger's method to get rid of the deformity at the inner canthus of the eye, and to try the author's previously devised "muscle substitution" method which he had employed

only upon the cadaver, to relieve the ptosis of the left upper eyelid. The left eyebrow was shaved and an incision carried from the root of the nose along the superciliary ridge almost to the external angle of the frontal bone. From the nasal extremity of this cut a vertical incision was made through the tissue of the forehead almost to the hair line. The flap was turned upward and outward so as to expose the occipito-frontal muscle and tendon. Just beneath the upper orbital margin an incision down to the fascia of the upper lid was made from the nasal to the temporal side following the curve of the bone. The skin flap was turned downward and the tarsal plate exposed and its upper edge identified. A tunnel was then cut beneath the soft tissues about half an inch in width extending under the orbicular muscle to the incision made through the shaved eyebrow. From the muscular belly of the occipitofrontal muscle, immediately about the tunnel opening, was cut a strip of muscular fibers about a third of an inch wide and an inch and a quarter long. The parallel incisions, making this strip, diverged a little at their upper ends so as to make the muscular band wider near its upper extremity. A cross incision was made at the upper end converting the strip into a long flap. This flap was turned downward, thrust through the tunnel, and attached to and upon the upper edge of the tarsal plate by three silk sutures. The two corner sutures were put in as mattress stitches and held the flap on top of it—that is, superficially to the tarsal fibrous plate. Returning to the frontal region, the operator cut on each side of the turned down flap two strips of muscle, each half the width of the inverted flap, having their attachment to the muscle above. These were drawn toward the fold of the inverted flap, attached to it on its superficial surface, which formerly had been the under surface, by a mattress suture at each edge, and were united in the middle line by a third suture, also put through the turned over portion of flap so as to make a mattress suture. An additional suture was inserted at one edge where the first flap was bent over to keep it thus folded. The skin and superficial flap of the forehead were then replaced and sutured in position by worm gut sutures. The result of the operation was excellent, although the time has been but four weeks. Subsequently the Berger operation with arrowhead excision on each side will be performed for the epicanthus. The sutures were so placed as to lift a little the canthus of each eye. The wound all healed by first intention. In addition to the ability to raise the eyelid a satisfactory result of the operation was the making of a normal furrow in the lid at the seat of the upper edge of the tarsal plate. It was suggested that if the incision through the eyebrow to that at the middle line of the forehead for any reason seemed to be undesirable, the flap might be turned outward and downward instead of outward and upward by making the horizontal incision within the hair line instead of in the eyebrow.

Birth Traumatisms of the Upper Extremity; The So-called Birth Palsies.—Dr. G. G. Davis in this paper stated that until comparatively recently injuries of the upper extremity, commonly called birth palsies, had been regarded by him as true nerve paralyses. Even at the present time the pathology of the injuries and their treatment were perhaps not definitely settled, although much had been accomplished. To his mind the greatest advance had been made by Dr. T. Turner Thomas, who, while not denying the occasional existence of distinct nerve lesions, had claimed that the main element of the lesion was articular, and to be treated by operative means. Dr. Davis had long been convinced that the essential element was an articular lesion and that the most successful treatment must be based upon this fact. He was not yet convinced, however, that the luxation described by Duchenne, treated by manipulation by Whitman, and operation reduction by Thomas, was the essential lesion of disability. While treatment of the luxation had been of value, he attributed the improvement in function to the changes produced in the soft parts by the operation. From his experience he believed that the condition consisted usually of lesions of the nerves, muscles, and ligaments about the affected parts, the extent and character of which varied with the mode of production of the original injury and the length of time after birth that the patient came under observation. Operations upon the brachial plexus have shown that absolute rupture of some of the nerves did take place, although rarely. The paralytic symptoms observed were usually due not to a rupture, but to a contusion or stretching of the nerves, under which circumstances the probability of recovery was excellent. There was too often the tendency in a young infant to consider the nerve lesion the prominent factor, when the quietude of the arm was due almost or quite entirely to the articular lesion, the remaining disability after healing of the contused nerves, was due to the cicatricial and damaged condition of the articular structures. This fact, unfortunately, was not generally recognized and the necessity of treating the condition was consequently ignored and a crippled arm might remain through life. In treatment obviously efforts should be made at the earliest possible moment. Delay in operative treatment in the very young, because of the problem of nourishment, might have no effect upon the nerve lesions but was decidedly harmful to the articular lesions. The essential part of treatment was said to be first to stretch or manipulate the parts that they might be placed in their normal positions by passive motion, with restoration of muscular power by training and exercise. Operative measures which might later become necessary because of fibrous obstructions and continued abnormal position of the limb would, of course, vary with individual cases. The good results following operation upon so-called luxations in these cases Dr. Davis attributed to the free division of the restraining tissues and the placing of the parts in better position and not to replacement of the head of the humerus. To his mind, conditions which had been termed luxations were rather sub-luxations, and the malposition in itself seemed scarcely of sufficient extent to account for the disability or to justify the expectation of much functional improvement by its correction. For the restricted motions in the shoulder joint, those of abduction and external rotation the operation employed by Dr. Davis was described and in the few cases in which he has used it marked improvement was obtained. He regards it as neither crippling nor dangerous. Operation upon the elbow for increasing flexion or extension was not regarded as advisable. In one patient aged about twenty, in whom supination was impossible, an incision was made over the middle of the radius and the insertion of the tendon divided. This allowed an additional degree of supination but not enough, and another incision was then made over the head of the radius, the external lateral and orbicular ligaments divided and the tissues detached for a short distance down the inner side of the neck and shaft. Upon supinating the hand, the head of the radius rose directly out of its bed and projected forward. Apparently the radius in its growth had become twisted so that when supination was performed the head was thrust forward. Therefore, the head and neck were removed nearly or quite down to the insertion of the biceps muscle at the radial tubercle. Dr. Davis urged the use of the greatest care in this procedure not to wound the posterior interosseous nerve. After closure of the wounds the forearm was dressed on a splint with the hand in extreme supination. In the one case in which the author had done this operation the results were extremely satisfactory. Attention was called to the possible prevention of many cases of injuries at birth and to the responsibility of the attendant; further, that the profession, since these injuries and their treatment are better understood, should cease to ignore them, and see that they receive efficient treatmnt.

Dr. T. Turner Thomas, remarking upon the etiology of birth palsies, said that it had been but a few years since there was but the one view that they were due to injuries of the brachial plexus; to-day many believed them due to injuries of the skeleton; thus was the profession reverting to the position of Duchenne in the beginning of his work upon this subject.

Dr. A. P. C. Ashhurst, relative to the frequency of the condition, said that in addition to the cases seen with Dr. Davis in his clinic, he had within the last two or three years nearly forty cases under his care. Of this number a large proportion had been shoulder dislocations. It was the dislocation of the shoulder to which Dr. T. T. Thomas called particular attention which had first aroused Dr. Ashhurst's interest in these conditions and given a clue to the best means of their treatment. In a child of three months in whom a posterior dislocation was confirmed by *x*-ray treatment was instituted as would be indicated in the same condition in the hip. Reduction was done under ether, and the shoulder held in a plaster dressing in abduction and external rotation. Dislocations, however, were not the only lesions occurring, and the dispute at present was whether the dislocation was caused by the original injury at birth, or followed a traumatic paralysis of

the shoulder muscles. Up to three years of age Dr. Ashhurst had secured permanent reduction without open operation, but in cases over this age recurrence had followed bloodless reduction. In none of the five cases in which he had operated by bloody reduction had dislocation recurred. In all he had used the approach to the shoulder joint described by Kocher with Senn's modification of the skin incision. In Dr. Ashhurst's opinion, if patients were treated from the time of birth, as emphasized by Dr. Davis and in the way he advised, most would recover with little permanent disability; that in a few of these cases at a later period, and in almost all seen for the first time a number of months after birth (especially if dislocation of the shoulder were present) it would be necessary to treat the upper extremity in plaster of Paris in abduction and external rotation for a period of not less than three months; that dislocation should be reduced, if necessary under anesthesia, as soon as practicable after its recognition; that in patients over three years of age, bloodless reposition seldom would be permanently successful; that operative treatment must secure anatomical reposition of the humerus in the glenoid, with restoration of free external rotation and abduction, which should be maintained by fixed dressings for a period of not less than three months; that in the vast majority of cases nerve lesions were insignificant, requiring no special treatment.

Dr. DAVIS, in closing, observed that while at the present the matter of pathology and treatment was unsettled much could be done for the improvement of cases. In spite of the fact that some of his cases exhibited were not brilliant from a demonstrative standpoint, from a utilitarian standpoint they were well worth the time and effort expended upon them.

The Use of the Karell Cure in the Treatment of Cardiac, Renal, and Hepatic Dropsies.—Dr. EDWARD HARRIS GOODMAN regarded drugs, physical therapeutics, and diet in the treatment of these conditions as the triad upon which reliance was usually placed, and believed that, generally speaking, in the lay as well as in the professional mind, the greatest of these was drugs. In many dropsical cases all three agents were indicated; in many, physical measures might be safely dispensed with; and, in very many cases of severe renal and cardiac breakdown, drugs as well as physical measures might be disregarded. There were no cases, however, in which diet had not earned a well-deserved fixed place. The majority of cardiac dropsies and a large proportion of dropsies of renal origin he believed would improve under rest in bed and an appropriate diet. The diet which had served him best, and which he had employed successfully for the past seven years, was that known as the Karell diet or Karell cure. Although half a century had elapsed since Karell had published his paper, this diet seemed to be but little known and but rarely used. Under the technique of the treatment the patient should receive daily at 8, 12, 4, and 8, 200 c.c. of raw or boiled milk, warm or cold, and no other food. Thirst formed the greatest cause of complaint during the first three or four days, and it might be necessary to allow the patient to rinse out his mouth with water. If hunger were urgent a small piece of toast or zwieback might be given with each portion of milk. The rapid loss of weight encouraged the patient to persist with the treatment. Continuance of the diet depended upon the diminution of edema and the patient's plea for more food. Usually the diet might be increased at the end of a week by giving a soft boiled egg (without salt or pepper) at 10 A.M. and a piece of zwieback at 6 P.M.; the next day, an egg at 10 A.M. and at 2 P.M. with a piece of white bread. Following this the food should be increased gradually to a full diet. Such "full diet," however, was a misnomer, since it should be salt poor and comprised of selected foods. Until the patient received the full diet the daily amount of liquid (which should be milk) must not exceed 800 c.c. Entering upon the full diet cocoa or tea might be substituted for the milk, limited to the same amount, however; such limitation was to be continued for from two to four weeks after the disappearance of edema. During the treatment the patient should be in bed. The bowels should be kept open; preferably by laxatives in pill form, since no water was required for their administration. Improvement should be noted at the end of three days. If this did not cure, drugs and other measures were indicated. Twelve illustrative cases of the effect of the Karell cure in edema were reported. The first three charts showed only loss of weight; the fourth, a rapid increase of diuresis, then a decrease indicating the need of other therapeutic measures; the fifth and sixth, loss of weight and increase of diuresis amounting to 531 ounces in four days with unusually rapid loss of weight; the eighth, the effect of the milk diet in hepatic cirrhosis; ninth, the failure of the cure; tenth, lowering of blood pressure, systolic and diastolic; the eleventh, retention of chlorids on a salt poor diet, with prompt elimination of chlorids and increased diuresis on Karell cure plus caffein and hot packs; twelfth, curves of body weight, chlorids and urine. The minimum amount of work given to the human organism was regarded by Dr. Goodman as the most important feature of the Karell cure. The good effects were seen by the patient almost before being noted by the physician, and these effects were the reward of strict observance of the cure, viz: the taking of only 200 c.c. of milk at 8, 12, 4, and 8, the purpose of the treatment being immediately defeated were the milk taken at the pleasure of the patient, or in larger quantity. While an attempt had been to ascribe the benefits following the Karell cure to reduction in the amount of fluid, the minimum of salt contained in the milk, and to the melting of body protein, it would seem more probable to the author that several problems were involved: (1) Absolute rest in bed; (2) the low amount of fluid and food which also limited cardiac effort; (3) the low amount of sodium chloride; (4) a combination of the salt-poor diet and the low amount of fluid. To whatever factors the results were due, in dropsical conditions of renal, cardiac, and perhaps hepatic origin, the Karell milk diet given as taught by Karell was in Dr. Goodman's opinion the diet par excellence. While in the majority of cases drugs in combination with the Karell cure would be found unnecessary, in marked dyspnea, cyanosis, frequent and irregular pulse, such drugs as camphor, digitalis, strophanthus, caffeine, and morphine were indicated in emergencies. In the prognostic significance of the Karell cure a positive chloride balance was of unfavorable import. The treatment was regarded as contraindicated in the presence of symptoms of uremia since it had been shown by Senator and others that in such crisis the fluid intake should be greatly augmented to eliminate the toxic substance causative of uremia.

Dr. JAMES TYSON recalled that fact that some of the early work of Dr. S. Weir Mitchell included the use of the Karell diet, which possibly was also the foundation of his little book on "Fat and Blood." In 1884 Dr. Tyson had read a paper on "The Milk Treatment of Disease."

Dr. JAMES M. ANDERS observed that the Karell cure was much more used abroad than in America. In the opinion of His the cure was not only effective in renal and cardiac dropsy, but alleviated the disturbance in breathing and other distressing symptoms not dependent upon the edema present in many of these cases. Dr. Anders agreed with other authors upon the value of the treatment before actual decompensation had taken place; for example, in cases of aortic valvular disease showing simply premonitory symptoms, associated perhaps with a mild grade of arteriosclerosis. After positive involvement of the kidneys and the presence of uremia it would be altogether contraindicated. Dr. Anders did not advocate the use of the treatment in valvular disease with dropsy in which the kidneys were intact, but in all such cases felt there should be allowed more food of a higher caloric value with aid to elimination by other means such as rest, cardiac stimulants, etc. It seemed to him that the use of iron could be utilized to advantage in connection with the Karell cure, particularly in the lengthened periods of its employment recommended by Dr. Goodman. Following the recommendation of His, Dr. Anders' custom had been to give 1,000 c.c. for five or six days at intervals. He hoped that Dr. Goodman's paper would bring this subject to the attention of the profession.

Dr. CLIFFORD B. FARR remarked that one of the chief theoretical objections to the treatment was the insufficiency of the diet even for a patient in bed, and suggested the possible advantage of the addition of sugar of milk or cream to the measured amount of milk. This would bring the nutritive value more nearly to the proper level and add nothing to the amount of fluid or chlorides.

Dr. GOODMAN in closing said that some food was given after three to six days, during those days, however, the diet was limited to 800 c.c. of liquid in the form, preferably, of milk. He thought the addition of cream or sugar of milk would be of advantage.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

State Medical Board of the Arkansas Medical Society.

November 9 and 10, 1915.

(*Concluded from page 46.*)

BACTERIOLOGY.

1. (a) Give method of blood staining. (b) What is the normal blood count, and how is it affected by disease?
2. (a) What is the value of Widal's test for typhoid fever? (b) At what stage of the fever is it most reliable?
3. What general conditions predispose to bacterial infections?
4. (a) Give general method of procedure for staining bacteria. (b) What are counterstains?
5. (a) What is the most effective method of sterilization? (b) How are culture mediums sterilized?
6. (a) Describe in detail the process of finding tubercle bacilli in the urine. (b) Give method of determining the location of the infection. (c) From what other bacilli would you have to differentiate them?
7. Name some of the diseases of which the pneumococci may be the chief etiologic factor.
8. What culture-medium is essential in the growth of the organisms producing the following diseases: Cerebrospinal meningitis, gonorrhea, and diphtheria?
9. Mention five general or systemic diseases produced by microorganisms, and in connection with each give name and chief morphologic characteristic of organisms concerned.
10. What is the cause of difference in the virulence of diphtheria?

PRACTICE.

1. Name four types of malarial infection, and give treatment of remittent fever.
2. Give the etiology and treatment of acute tonsillitis.
3. Give the treatment for habitual constipation.
4. Differentiate between pleurisy with effusion and acute lobar pneumonia, giving treatment of the latter.
5. Give the treatment of facial erysipelas.
6. How would you make an early diagnosis of tuberculosis?
7. Give the treatment of ophthalmia neonatorum.
8. Give the treatment of convulsions caused by nephritis.
9. Give the medical treatment of ulcer of the stomach.
10. Give the symptoms and treatment of pellagra.

OBSTETRICS.

1. Into what stages is labor divided, and where do these stages begin and end?
2. Give diagnosis and management of a breech presentation. What are the dangers?
3. Give indications for the use of forceps, internal podalic version, and cesarean section.
4. What are the causes of hyperemesis gravidarum, and the clinical features and the treatment of the condition?
5. What is placenta prævia? Name its causes, varieties, symptoms, dangers, and treatment.
6. Eclampsia: etiology, premonitory symptoms, and treatment?
7. Describe the delivery of the placenta after the method of Credé.
8. Give two indications for the induction of premature labor, and describe one method of performing it.
9. What are the symptoms of inevitable abortion, and how should a case be managed?
10. How would you manage a case of primary postpartum hemorrhage?

GYNECOLOGY.

1. (a) Name two causes of sterility in the male. (b) Name three of sterility in the female.
2. Name the objective signs of extrauterine pregnancy.
3. Name two most common causes of dysmenorrhea.
4. What symptoms of cystitis are first noted?
5. Name the indications for the use of uterine tampons following abortion.
6. Name three varieties of fibroids of the uterus.
7. Name three etiologic factors in acute endometritis.
8. Give treatment for inoperable carcinoma of cervix.
9. Would you remove *in toto* an ovary with a small cyst?
10. What are the objections to ventral fixation of uterus?

SURGERY.

1. Define inflammation, septicemia, and pyemia. What organs are most prone to pyemia?
2. What general term denotes control of hemorrhage? State all the methods which may be used to stop the flow of blood from a wound.
3. What would be the proper treatment for backward dislocations of the femur at knee, with rupture of the popliteal artery?
4. Give causes, symptoms, diagnosis, and treatment for acute suppurative osteomyelitis.
5. Define shock, and state how you would treat same.
6. If called to a patient with a compound fracture of leg in lower third which had been produced by kick of horse in a barnyard, state in detail how you would treat such case.
7. Define ankylosis; give varieties; also describe a surgical method for restoration of joint function in case of bony ankylosis of the knee joint.
8. Give points of differential diagnosis between pyloric (or duodenal ulcer) and cholecystitis.
9. Give varieties of ileus, and state some of the causes of each.
10. Give symptoms, diagnosis, and treatment of stone in ureter.

HYGIENE.

1. Name four points in personal hygiene to prevent acquiring or imparting tuberculosis.
2. Name some special precautions a child should observe at school in order to avoid contracting disease.
3. What is the hygiene of pregnancy, and what advice would you give a pregnant woman from a hygienic standpoint?
4. Give prophylaxis of filth diseases.
5. What are the dangers from (a) the house fly? (b) The mosquito? (c) How would you exterminate them from a community?
6. (a) Name the chief sources of contamination of drinking water. (b) Give several methods of purifying drinking water.
7. Name some diseases that are communicated to man through cow's milk.
8. (a) Name all diseases due to microorganisms. (b) Methods of transmission.
9. What hygienic precautions should be employed around a patient with scarlet fever and diphtheria?
10. What necessary precautions should be taken to insure healthy sleep?

ANSWERS.

BACTERIOLOGY.

1. The film is properly made and fixed. It is then stained for five minutes with 0.5 per cent. alcoholic solution of eosin diluted with water; it is then rinsed in water, and dried with filter paper; it is then stained for half a minute with a saturated aqueous solution of methylene blue; and again it is rinsed and dried, and then mounted. The normal blood count is about 5,000,000 red corpuscles to the cubic millimeter, in women the number is about 4,500,000. The colorless corpuscles are about 6,000 to 10,000 to the cubic millimeter. The red corpuscles may be *increased* in: Chronic heart disease, with cyanosis; and in conditions in which the blood is concentrated owing to a severe watery diarrhea. The red corpuscles are *decreased* in: Anemia (particularly pernicious anemia) and leucocythemia. The colorless corpuscles are *increased* in: Leucocythemia, leucocytosis (due to inflammation, suppuration, toxins, etc.). The colorless corpuscles are *decreased* in conditions of starvation and malnutrition, and sometimes in pernicious anemia.
2. The diagnostic value of the Widal reaction is believed by some to be great; others place little reliance on it. It may be absent in cases of typhoid fever; it may be present for several months after an attack of typhoid; the reaction may not be obtained till the third week of the disease; it may be present in other diseases or in perfectly healthy persons. The above have all been urged as objections; certainly only positive results have any value at all. Enthusiastic advocates of it have asserted that it is present in over 95 per cent. of all cases of typhoid. It is probably most reliable during the second week of the disease.

3. *Conditions which predispose to bacterial infection:* The bacteria must be sufficiently virulent, must enter in sufficient numbers and by the appropriate avenue, and the host must be susceptible to their action. The latter condition is aided by anything which depresses or diminishes the general physiological activity of the host, such as depressing hygienic conditions, old age, weakness, extreme youth, fatigue, disease, exposure to cold, insufficient diet, intoxications of all kinds, the inhalation of harmful vapors, and traumatism.

4. *General method of staining bacteria:* "Nearly all the known bacteria are readily stained by the watery solutions of any of the basic anilin dyes. The film on the slide or cover-glass, properly prepared, is covered by a few drops of the stain, or the cover glass, *film-side down*, is floated in a watch-glass full of the staining solution; at the end of from one-half to two or three minutes the staining fluid is poured off, the slide or cover-glass washed rapidly in water and then allowed to *air-dry;* after which, in the case of cover-glass preparations, they are inverted upon a drop of Canada balsam on a slide and examined with the oil-immersion lens; or, when slides have been prepared, after washing and drying a drop of cedar oil is put over the preparation, and the same is examined with the oil immersion objective, without the use of a cover-glass."—(Archinard's *Bacteriology.*)

A *counterstain* is a stain used to bring into contrast bacteria or parts of tissues colored by another stain.

5. Heat is the best sterilizer; hot air or steam may be employed. Culture media are sterilized by steam in an autoclave, at a temperature of 110° C., at 6 pounds pressure, for half an hour. If an Arnold sterilizer is used the intermittent plan must be adopted, otherwise the spores will not be destroyed.

6. *To find tubercle bacilli in the urine:* "Withdraw the urine by a sterile catheter into a sterile conical urine glass. The urine so withdrawn is allowed to stand until the sediment collects. The supernatant fluid is poured off and the sediment is centrifuged. The supernatant fluid is poured out of the centrifuge tube, the tube filled with distilled water that is free from tubercle bacilli, shaken so as to wash out the urinary salts, which interfere with the staining, and centrifuged again. This process is repeated once or twice. The sediment remaining after the third centrifugation is smeared on clean glass slides and allowed to dry in the air. The smears are fixed by passing three times through the flame, and then stained for five minutes with warm carbolfuchsin, washed in water, submitted to the action of the acid-alcohol solution for one minute, washed in water, counterstained with Löffler's alkaline methylene-blue for thirty seconds, dried, and examined under a 1/12 inch oil immersion objective. If acid-fast bacilli are found by this method, a second smear should be decolorized in the acid solution overnight, washed in water, and counterstained in the Löffler's alkaline methylene-blue in order to be sure that they are not smegma bacilli. Urine obtained by the catheterization of the ureters may be treated in the same way."—(Anders and Boston's *Medical Diagnosis.*)

If tubercule bacilli are only found after ureteral catheterization, the lesion is not in the bladder, but in ureter or kidney. The cystoscope may show lesions in bladder or urethra. The tubercle bacilli must be differentiated from the smegma and leprosy bacilli.

7. *Pneumococci* may cause pneumonia; they may be found associated with other microorganisms in diphtheria, tonsilitis, otitis media, endocarditis, lobular pneumonia, pericarditis, meningitis, arthritis, osteomyelitis, and conjunctivitis.

8. *Cerebrospinal meningitis* is caused by the *Diplococcus intracellularis meningitidis;* it grows well on blood serum, ascitic fluid, and culture media containing meat infusion.

Gonorrhea is caused by the *Diplococcus gonorrhæ;* it grows on blood serum, or mixtures of meat infusion agar with blood serum or hydrocele or ascitic fluid.

Diphtheria is caused by the *Bacillus diphtheriæ;* it grows upon blood serum and meat infusions.

9. *Typhoid fever* is caused by the *Bacillus typhosus* of Eberth. This organism is rod shaped, with rounded ends, is from 2 to 4 mikrons in length, and about three-fourths of a mikron in breadth; it does not stain by Gram's method, but stains with all the anilin dyes; it has flagella, no spores, is aërobic and facultative anaërobic, and is motile.

The *characteristics of the bacillus of diphtheria* The bacilli are from 2 to 6 mikrons in length and from 0.2 to 1.0 mikron in breadth; are slightly curved, and often have clubbed and rounded ends; occur either singly or in pairs, or in irregular groups, but do not form chains; they have no flagella, are non-motile, and aërobic; they are noted for their pleomorphism; they do not stain uniformly, but stain well by Gram's method and very beautifully with Löffler's alkaline-methylene blue.

The cause of *syphilis* is the *Treponema pallidum.* It is a very slender spiral, about 4 to 20 mikrons in length, with very close and regular turns, the curves vary in number from three or four to twelve to twenty. At each pole is a fine flagellum. It can move forward and backward, and also rotate on its axis. It is not settled whether division is transverse or longitudinal. It has not yet been cultivated on artificial media.

Plague is produced by the *Bacillus pestis.* This is non-motile, with rounded ends, is about 1½ mikrons in length and a little more than half a mikron in breadth; it stains readily with all the anilin dyes, but not by Gram's method; it has no spores, and is not encapsulated.

Tetanus is produced by the *Bacillus tetani.* This is a small, slender rod with rounded ends; at one end is a spore, which gives the bacillus the appearance of a pin or a drumstick; it is from 2 to 4 mikrons long and from ¼ to ½ mikron in breadth; it is slightly motile, is anaerobic, and stains with the ordinary anilin dyes and by Gram's method.

10. *The difference in the virulence of diphtheria* may be due to the difference in the number of bacilli present, or to the variation in the tenacity with which they retain their virulence, or to variations in the body defenses and general vitality of the patient affected.

PRACTICE.

1. *Four types of malarial infection*:—Tertian (intermittent), quartan (intermittent), estivoautumnal (remittent), and malarial cachexia, or chronic malaria.

Treatment: "In the remittent estivoautumnal type it is often impossible to anticipate the paroxysms. The quinine must then be given at regular intervals and in sufficiently large doses to produce physiological effects in the shortest time possible. It often happens, particularly in the pernicious form, that the remedy is not retained, or, if retained, it fails to produce the desired effect, more especially when it is administered in capsule or cachet. It is then better to administer it hypodermically in the form of the hydrobromide, hydrochloride or bisulphate, in doses of 15 to 30 grains once or twice a day. The method advocated by S. Solis-Cohen is to give but three subcutaneous injections of 10 or 15 grains (0.65-1.0) during seven days following the last paroxysm, repeating the injection, however, after each paroxysm, in the event of recurrence. Unfortunately there is great liability to cause abscesses by this method.

It is of the utmost importance in this form of infection to get the gastrointestinal canal into a condition favorable to the absorption of quinine. A calomel or blue-mass purge, followed, if necessary, by a full dose of magnesium sulphate, often seems to double the effect of the previously ineffective doses of quinine, and Warburg's tincture often arrests a remittent fever on which much larger doses of quinine in other forms have had no influence. It should be given in doses of ʒ ss every two or three hours. In some instances the use of one of the more soluble salts by internal administration will be found more effective than that of the sulphate."—(French's *Practice of Medicine.*)

2. Acute Tonsillitis. *Etiology*: The *Staphylococcus pyogenes* and *Streptococcus pyogenes* are the chief organisms found; acute rheumatism is often associated with the disease. Predisposing causes are exposure to cold and wet, and poor hygiene. *Treatment*: Rest in bed; a calomel purge followed by a saline; salicylates gr. x-xv every three hours, or tincture of aconite; liquid diet; antiseptic sprays, and cold applications.

3. *Treatment of chronic constipation:* "The cultivation of habits of regularity is of the utmost importance. The patient should go to stool at the same time every day, whether there is a desire to evacuate the bowels or not, and every such desire should be immediately gratified. The diet should comprise considerable fruit and vegetables (which leave a residue). A glassful of cold water before breakfast, an orange or oatmeal at breakfast, and stewed fruits and salads at dinner subserve a useful purpose in many cases. Persons of sedentary habits are often benefited by exercise; abdominal massage is useful in some cases, and an abdominal binder is of value to those with a pendulous flabby abdomen and visceroptosis.

Drugs should be dispensed with as long as possible. Medicinal measures when necessary vary with the nature of the causal factor, which must be diligently searched for. At the beginning of the treatment it is often advisable to clear the intestine thoroughly with castor oil, a blue mass pill or calomel followed by a saline aperient. In many cases the best results are obtained by a daily injection of tepid water with or without soap; in other cases injections of oil are much better; but enemas should not be too long continued. Some patients are much benefited by a saline aperient water, sodium phosphate, or other saline, taken a half hour before breakfast. Should a course of medicine be necessary, the desired results may usually be secured by the use of cascara sagrada, which has the advantage that, having been continued for some time, the dose necessary to secure a daily evacuation may be gradually reduced, and the drug ultimately dispensed with, should the patient continue habits of regularity. The pill of aloin (⅛ grain), strychnine (1/40 grain), and extract of belladonna (1/10 grain), though much abused, is very useful in many cases."—(Kelly's *Practice of Medicine.*)

4.

PLEURISY WITH EFFUSION.	LOBAR PNEUMONIA.
Onset marked by chilliness persisting for a few days.	Onset acute, with rigor, lasting one hour or longer.
Cough is irritating; no expectoration, or, if present, catarrhal in character.	Cough more marked, and accompanied by rusty or bloody, tenacious expectoration.
Sputum negative; tubercle bacilli rare.	Dense aggregations of pneumococci present.
Moderate fever of continuous type; declines by lysis.	Fever, 102° to 104° F.; falls by crisis.
Prostration moderate.	Prostration extreme.
Unilateral distention of the thorax.	Absent.
Countenance pale and anxious.	Mahogany-colored flush of cheeks.
Limited expansion at base of chest on the affected side.	Degree of expansion slightly, if at all, inhibited.
Tactile fremitus diminished or absent.	Increased over area of consolidation.
Interspaces bulging at base of chest.	Absent.
Percussion shows flatness, with great resistance to the pleximeter finger.	Dullness with less resistance, and sometimes a tympanitic note.
Diminished or absent breath-sounds over effusion the rule. Respiration murmur diffuse, distant, and generally unaccompanied by rales. Bronchial breathing may be present over the entire affected side of the chest.	Harsh bronchial breathing and presence of rales in first and third stages, unless a bronchus is plugged.
Friction sound heard in early and late stages.	No friction murmur; rales present.

(Anders and Boston's *Medical Diagnosis.*)

The *treatment of pneumonia* "depends entirely on the type of case, and the condition of the patient. Routine treatment is the worst of all treatments. Answer the following questions before prescribing: Is the patient full-blooded, and is there a full bounding pulse? Is the pulse feeble, irregular, or intermittent?

"In the first case, in a young and previously healthy adult, if there be cyanosis, or signs of dilatation of the right heart, blood-letting to the extent of a few ounces may perhaps relieve the strain, but more generally treatment should be directed to maintaining the strength from the outset.

"In the latter case we can hope for nothing from a depressing treatment, so stimulants must be resorted to, such as alcohol, ammonium carbonate, egg and brandy mixture, quinine, ether, etc. The giving or withholding of alcohol depends upon its effect upon the pulse; should the pulse rate fall and the tongue become moist it may be continued. In asthenic cases, strychnine hypodermically is necessary from the outset and normal saline may be given by the rectum or by the skin. Oxygen inhalations are used where there is cyanosis, but it is doubtful whether they have saved many lives. When there is evidence of failure of the heart (weakness of the second pulmonary sound, etc.) digitalis should be resorted to. Many prescribe it from the outset.

"The diet should consist of milk, beef-tea or broths, white of egg, and so on. The patient should be as little moved as possible, and the bed-pan must be used. As in other fevers, an airy room and good nursing are essential.

"Remember that narcotics are not well borne in respiratory embarrassment as a rule. Chloral should be avoided, but *if pain be excessive* a hypodermic injection of morphine does *more good* than harm, notwithstanding that theoretically morphine is contraindicated. It should not be given later than the first few days of the illness. The pain may also be relieved by poultices, which, however, are of doubtful use if carelessly made, or by application of ice. Cold packs applied to the trunk only, and frequently repeated are very useful in relieving both pain and fever. Depressant antipyretics are to be avoided.

"The results of *serum treatment* are not unequivocally encouraging but vaccine treatment would seem to be of better promise. Where possible, an autogenous vaccine should be used." (Wheeler and Jack's *Handbook of Medicine.*)

5. *Treatment of facial erysipelas* includes isolation of the patient, and antisepsis; light and nutritious diet, and tonics and stimulants are indicated; tincture of the chloride of iron, ηχv in water, thrice daily; ichthyol ointment, 15 to 20 per cent, may be applied; antistreptococcus serum has been tried.

6. The early manifestations of pulmonary tuberculosis are: (1) *Physical signs:* Deficient chest expansion, the phthisical chest, slight dullness or impaired resonance over one apex, fine moist rales at end of inspiration, expiration prolonged or high pitched, breathing interrupted. (2) *Symptoms:* General weakness, lassitude, dyspnea on exertion, pallor, anorexia, loss of weight, slight fever, and night sweats, hemoptysis.

7. The *treatment of ophthalmia neonatorum* is: (1) *Prophylactic:* Whenever there is the possibility of infection, or in every case, wash the eyelids of the new-born child with clean warm water, and drop on the cornea of each eye one drop of a 1 or 2 per cent. solution of nitrate of silver, immediately after birth. (2) *Remedial:* Wash the eyes carefully every half hour with a saturated solution of boric acid; pus must not be allowed to accumulate. Two drops of a 2 per cent. solution of nitrate of silver must also be dropped on to the cornea every night and morning. The eyes must be covered with a light, cold, wet compress. The patient must be isolated, and all cloths and compresses used must be burnt.

8. *Treatment of convulsions caused by nephritis:* Chloroform during convulsions, wet cupping, venesection if patient is otherwise robust, hot pads, free purgation, pilocarpine to produce sweating (only if there is no edema); the food must be nutritious (chiefly milk), but nitrogenous food in general must be avoided; salt, stimulants, and diuretics are prohibited; the patient should have sufficient water to drink.

9. *Medical treatment of gastric ulcer:* Rest and a light and easily digested diet are absolutely essential. Abstinence from food by stomach and gastric lavage with feeding may be necessary for a time. Sodium bicarbonate, bismuth subnitrate, silver nitrate and opium are the most frequently used drugs. Pain, vomiting, and hemorrhage are treated as they arise; perforation demands prompt operative interference.

10. In *pellagra* "the symptoms develop insidiously, the earliest manifestations usually being gastrointestinal—anorexia, stomatitis, salivation, epigastric pain or distress, diarrhea and a gradually increasing anemia, disinclination to exertion, and psychic depression. The fully developed disease is characterized by cutaneous, digestive, and nervous symptoms. There is at first a characteristic pellagrous erythema that usually comes on first in the spring, tends to subside and recur (in the fall and spring). It develops bilaterally especially on the exposed surfaces, the hands, arms, face, and neck; that is, it seems to be related to the action of the actinic rays of the sun; it may be dry (usually early) or wet; the lesions become pigmented (liver yellow or chocolate color) and usually progress to desquamation, exfoliation, and gangrene of the skin, which are followed by cicatrization. The characteristic digestive symptoms consist of stomatitis, the cardinal red tongue the bald tongue or the stippled, bluish black tongue; salivation, pyrosis, and diarrhea (fetid, slimy, greenish stools), sometimes bloody stools, may occur. The nervous symp-

toms consist of neuromuscular pains in the back and legs, spinal tenderness, headache, vertigo, unilateral or bilateral mydriasis, muscular spasms, exaggerated reflexes, later paralysis with lessened or absent reflexes, mental depression delusions, hallucinations, melancholia, and insanity. Mild cases may be afrebile, but fever (102° to 105° or more) is not uncommon. Improvement may occur after the lapse of several months, but recurrences especially in the fall and spring are common."—(Kelly's *Practice of Medicine.*)

The *treatment* is mainly symptomatic; liberal diet, and proper hygienic surroundings are indicated; fresh fruit, milk, eggs, fresh peas or beans, lean meat. The drug which has given the best results is arsenic (Fowler's solution, soamin, salvarsan, or atoxyl). Change of climate may bring about improvement.

OBSTETRICS.

1. Labor is divided into three stages: The *first stage* begins with the commencement of labor, and ends with the complete dilatation of the os uteri. The *second stage* begins with the complete dilatation of the os uteri, and ends with the birth of the child. The *third stage* immediately follows the second, and ends with the expulsion of the placenta and the beginning contraction of the uterus.

2. *Diagnosis of breech:* Abdominal palpation reveals the head above and the breech below. The heart-sounds are heard above the umbilicus. Vaginal examination shows high position of the presenting part, and when the os is dilated the characteristic features of the breech may be detected. Meconium is evacuated.

Management: First stage.—Keep the patient in bed and at rest, so as to preserve the membranes as long as possible. Warn the relatives of the risk to the child. *Second stage.*—Prepare warm towels to wrap around the child's body and limbs, and a warm bath, and everything likely to be required for the treatment of asphyxia. Allow the breech to be born without hurrying it. Support the perineum as in a vertex case. As soon as the body is born as far as the umbilicus, draw down a loop of the cord, at the same time maneuvering it to the corner of the pelvis, where it is least likely to be compressed. This loop by its pulsations is an index of how it is faring with the child. Wrap the limbs and trunk in a warm towel, and hold them slightly towards the mother's abdomen so as to aid the lateral flexion of the body. At the same time exert suprapubic pressure upon the fundus which aids expulsion and promotes flexion. When the elbows appear the hands may be gently disengaged with the finger. Meantime carefully watch the pulsations of the cord. Provided it is beating regularly and the child is not making convulsive movements, there is no need for anxiety. Wait for the next pain and with the aid of suprapubic pressure expel the head in a fully flexed attitude. *Extraction of the head.*—If the head be delayed more than a few minutes after the birth of the trunk as far as the umbilicus, it will almost certainly require to be artificially aided. The two best methods of doing this are (1) the Prague seizure, and (2) the Mauriceau-Smellie-Veit grip. Both are designed to extract while at the same time promoting flexion. Therefore aid the latter by making the nurse or assistant exert suprapubic pressure while the extraction is being performed. Either method is more easily performed if the mother is in the cross-bed position on her back. This position can only be maintained by the aid of assistants, but if such aid is available it is often desirable to place the mother in this position as soon as the breech reaches the vulva. Anesthesia is also required. *Prague seizure.*—Seize the feet and legs by one hand and carry them well forward between the mother's thighs. Place the first and second fingers of the other hand over the child's shoulders to steady the head. Pull upon the legs in a direction at right angles to the mother's abdomen. This forces the occiput against the pubes and so increases flexion, while it also effects extraction, which is controlled by the fingers over the shoulders. In a primipara this method may require such force that the head comes out with a suddenness that causes severe tearing of the perineum. In these cases the second method is perhaps better. *Mauriceau-Smellie-Veit grip.*—Place the child astride upon the left forearm, and slip the two first fingers of the left hand into the vagina and apply them to the superior maxilla on each side of the nose. With these fingers try to draw down the chin and nose, and so promote flexion. At the same time the two first fingers of the right hand are passed over the shoulders and traction made by them in an upward direction. An alternative is to pass the left forefinger into the mouth, but this is apt to cause injury to the jaw."—(*Johnson's Midwifery.*)

The danger to mother and child in a case of breech presentation are: (1) Compression on the umbilical cord; (2) premature respiration; (3) asphyxiation of the child; (4) the child may suffer from fractures, dislocation, hemorrhage, or paralysis; (5) extension of the head, or of the arms over the head; (6) increased tendency to rupture of the perineum.

3. *Indications for the use of forceps* are: "1. *Forces at fault:* Inertia uteri in the presence of conditions likely to jeopardize the interests of mother or child. (*a*) Impending exhaustion; (*b*) arrest of head, from feeble pains. 2. *Passages at fault:* Moderate narrowing 3¼ to 3¾ in., true conjugate; moderate obstruction in the soft parts. 3. *Passenger at fault:* A. Dystocia due to (*a*) occipito-posterior, (*b*) mento-anterior face, (*c*) breech arrested in cavity. B. Evidence of fetal exhaustion (pulse above 160 or below 100 per minute.) 4. *Accidental complications:* Hemorrhage; prolapsus funis; eclampsia. All acute or chronic diseases or complications in which immediate delivery is required in the interest of mother or child, or both.—From Jewett's *Practice of Obstetrics.*)

The indications for podalic version are: (1) In transverse presentations; (2) in placenta prævia; (3) in malpresentations of the head; (4) in simple flattened pelvis, and in minor degrees of pelvic contraction; (5) in prolapsus funis; (6) in sudden death of the mother; and (7) in any case where speedy delivery is imperative.

The *absolute indications for cesarean section* are: Extreme pelvic contraction or deformity in which delivery by forceps or version or symphyseotomy is impossible, and in which craniotomy is either impossible or would be more dangerous to the mother; the presence of extreme atresia of the vagina; rupture of the uterus; sudden maternal death.

4. *Hyperemesis gravidarum* is occasionally seen in pregnancy, and becomes "so excessive as to threaten the patient's life. It may arise from a variety of causes. The most common are: Reflex disturbance, caused by the rapid growth and distension of the uterus; some pathological condition of the uterus or its adnexa; some pathological condition of the gastrointestinal tract; excessive sexual intercourse; kidney insufficiency. The principal symptom is continuous vomiting, which results in exhaustion and death unless relieved. The outlook is very grave. The *treatment* consists in rest in bed in a quiet, darkened room and the administration of easily digested foods, such as milk, broths, eggs, etc. A careful search must be made for some local exciting cause, and if any such condition is found it should receive appropriate treatment. Sexual intercourse should be interdicted. The bowels should be kept freely open. Sodium bromide, camphor, cocaine, silver nitrate, cerium oxalate, hyoscine, hydrobromide, antipyrin, etc., are among the drugs used internally. Rectal alimentation may be necessary, and, as a last resort, dilatation of the cervix and internal os, or abortion may be performed."—(*Pocket Encyclopedia.*)

5. *Placenta prævia* is the condition in which the placenta is attached in the lower uterine segment and may be near or over (partially or completely) the internal os. The *causes* are unknown; multiparity, frequent pregnancies with subinvolution, and abnormalities of uterus, placenta or cord are said to predispose to this condition. *Varieties:* (1) *Central,* when the placenta completely covers the os. (2) *Partial,* when the placenta overlaps the os. (3) *Marginal or lateral,* when the placenta reaches the margin of the os but does not overlap it. *Symptoms:* Sudden hemorrhage, accompanied by syncope, vertigo, restlessness, and feeble pulse. *Dangers:* Hemorrhage, sepsis, death of the mother, death of the fetus. *Treatment:* Stop the hemorrhage by a tampon; this must be tight and thorough. *Accouchement forcé* is indicated; this consists of dilatation of cervix, version and immediate extraction of the child.

6. PUERPERAL ECLAMPSIA is an acute morbid condition, occurring during pregnancy, labor, or the puerperal state, and is characterized by tonic and clonic convulsions, which affect first the voluntary and then the involuntary muscles; there is total loss of consciousness, which tends either to coma or to sleep, and the condition may terminate in recovery or death. *Etiology:* Uremia, albuminuria, imperfect elimination of carbon dioxide by the lungs, medicinal poisons, septic infection; predisposing causes are renal disease and imperfect

elimination by the skin, bowels, and kidneys. *Premonitory symptoms:* Headache, nausea, and vomiting, epigastric pain, vertigo, ringing in the ears, flashes of light or darkness, double vision, blindness, deafness, mental disturbance, defective memory, somnolence; symptoms easily explained by the circulation of toxic blood through the nerve centers. These may be preceded by lassitude, and accompanied by constipation, or by diarrhea. Headache is perhaps the most significant and common warning symptom. In bad cases the urine is reduced in quantity (almost suppressed), very dark in color, its albumin greatly increased, so that it becomes solid on boiling. Next comes the final catastrophe of convulsions. For *preventive treatment:* (1) The amount of nitrogenous food should be diminished to a minimum; (2) the production and absorption of poisonous materials in the intestines and body tissues should be limited and their elimination should be aided by improving the action of the bowels, the kidneys, the liver, the skin, and the lungs; (3) the source of the fetal metabolic products and the peripheral irritation in the uterus should, if necessary, be removed by evacuating that organ. The *curative treatment* includes: (1) Controlling the convulsions (by chloroform, veratrum, or chloral); (2) elimination of the poison or poisons which are presumed to cause the convulsions; (3) emptying the uterus under deep anesthesia, by some method that is rapid and that will cause as little injury to the woman as possible.

7. *Crede's method of delivering the placenta* "is to reinforce the expulsive strength of the uterine contractions by grasping the fundus through the abdominal wall, with the thumb in front and the fingers behind, and, at the acme of the pain, not sooner, compress the fundus firmly downward in the axis of the birth canal. The fundus should be carried well back during the manipulation to bring the uterine axis more into the line of the vaginal axis. This process may be repeated with each pain, at the acme of the contraction, until the placenta is delivered. Vaginal bleeding will appear in the interval between contractions when the placenta begins to separate. This bleeding is from the placental site which cannot retract until the placenta is completely detached. No traction should be made on the cord to assist the delivery of the placenta. Occasionally when the placenta is in the vagina or in the grasp of the lower segment, funic traction is admissible. The separation and expulsion of the placenta from the upper, contracting segment of the uterus may be recognized by an upward movement of the fundus, as the placenta passes into the lower segment and vagina."—(Polak's *Obstetrics.*)

8. *Two indications for the induction of premature labor:*—Placenta prævia, and toxemia of pregnancy. It may be accomplished by introducing a catheter, under proper aseptic and antiseptic percautions, between the membranes and the lower uterine segment; care must be taken to avoid rupturing the membranes; more than one catheter may be inserted; the instrument is left to be expelled with the child.

9. *Symptoms of inevitable abortion:*—Hemorrhage, severe cramps, dilatation of cervix, uterus soft and enlarged, the discharge consists of dark blood, clots, and portions of the ovum.

Management of inevitable abortion: "Two methods of treatment have been advised for these cases. The first is *the expectant plan:* Place the patient in bed, and if the bleeding is profuse insert a tampon of iodoform gauze (one yard) well up against the cervix. If this fails to control the hemorrhage, reinforce it by another yard or two of gauze and a perineal pad and binder. Small doses (5½) of the fluidextract of ergot should now be given every two or three hours. At the end of from eight to twelve hours remove the tampon, when the ovum may be found extruded from the cervix; if not, a vaginal douche of mercuric chloride (1:4000) must be given, and another tampon introduced. If, upon the removal of this second tampon at the end of ten or twelve hours, the ovum is not discharged, then more vigorous methods to secure its expulsion must be adopted. *Active plan:* The physician's hands and instruments are sterilized; the patient is etherized and placed on an approprite table; the genitalia are thoroughly cleansed and a vaginal douche of mercuric chloride (1:4000) is given; the anterior lip of the cervix is brought down to the vulvar orifice; the cervix is dilated if necessary; the placental forceps is introduced into the uterus, and as much as possible of the ovum is removed; the uterus is thoroughly curetted, and an intrauterine douche of sterile water is given. A light tampon of iodoform gauze is placed in the vagina; the patient is then returned to bed. A strip of gauze may be placed in the uterus in cases of sharp retroflexion, to secure free drainage, and occasionally an intrauterine tampon will be necessary, when the uterus refuses to contract and hemorrhage persists after the use of the curette."—(*Pocket Cyclopedia.*)

10. *Treatment of postpartum hemorrhage.*—Grasp the uterus at once, through the abdominal wall, and massage it firmly. Anything in the uterus should at once be cleaned out. Pass one hand into the uterus, and with the other on the outside make firm pressure. A hypodermic of ergotin, or ergot can be given by an assistant. An intrauterine douche of hot sterilized water (about 115° F.) may be given. Sometimes a very thorough packing and plugging of gauze of uterus and vagina may be necessary. Whatever is done must be done promptly; and everything likely to be needed for this emergency should be prepared beforehand in every labor.

GYNECOLOGY.

1. *Two causes of sterility in the male:*—Abscess of virile spermatozoa, and hypospadias.

Three causes of sterility in the female:—Abscess of uterus, tubes or ovaries; atrophy of uterus or ovaries; and gonorrhea.

2. *Objective signs of extrauterine pregnancy:*—"When extrauterine pregnancy exists there are: (1) The general and reflex symptoms of pregnancy; they have often come on after an uncertain period of sterility; nausea and vomiting appear aggravated. (2) Then comes a disordered menstruation, especially metrorrhagia, accompanied with gushes of blood, and with pelvic pain coincident with the above symptoms of pregnancy; pains are often very severe, with marked tenderness within the pelvis; such symptoms are highly suggestive. (3) There is the presence of a pelvic tumor characterized as a tense cyst, sensitive to the touch, actively pulsating; this tumor has a steady and progressive growth. In the first two months it has the size of a pigeon's egg; in the third month it has the size of a hen's egg; in the fourth month it has the size of two fists. (4) The os uteri is patulous; the uterus is displaced, but is slightly enlarged and empty. (5) Symptoms No. 2 may be absent until the end of the third month, when suddenly they become severe, with spasmodic pains, followed by the general symptoms of collapse. (6) Expulsion of the decidua, in part or whole. Nos. 1 and 2 are *presumptive signs;* Nos. 3 and 4 are *probable signs;* Nos. 5 and 6 are *positive signs.*"—(*American Text-Book of Obstetrics.*)

3. *Two common causes of dysmenorrhea:*—Pelvic congestion and underdevelopment or lack of development of the genital organs.

4. *Early symptoms of cystitis:*—Vesical tenesmus, frequent urination, pain, urinary changes.

5. A uterine tampon may be necessary after an abortion if the uterus does not contract, and if the hemorrhage continues after curettage.

6. *Three varieties of fibroids of the uterus:*—Interstitial, submucous, and subperitoneal fibroids.

7. *Three etiologic factors in acute endometritis:*—Sepsis following labor or abortion, gonorrhea, and instrumental interference with the uterus.

8. *Treatment for inoperable carcinoma of cervix:*—Careful nursing, scrupulous cleanliness with douches containing potassium permanganate or bichloride of mercury; morphine for the pain; the dead tissue may be removed by scissors or curette; tonics and nourishing food are indicated.

9. "The *treatment of an ovarian cyst* is ovariotomy by the abdominal route. The tumor should be removed at once, as there is less danger in operating upon a small pelvic tumor than a large abdominal growth which has undermined the general health and formed adhesions with adjacent organs."—(Ashton's *Gynecology*).

10. *The objections to ventral fixation of the uterus* are thus given by Hermann (*Students' Handbook of Gynecology*):

"(1) Its risk. Oversights will occur in the practice even of the most careful; but the risk is very small. (2) Adhesions within the peritoneum are sometimes absorbed. They are absorbed often enough to make stitching of peritoneum to peritoneum unsatisfactory. After abdominal section ventral hernia may first develop after the scar has held firm for twelve years; and possibly the new attachment of the uterus may also, after many years, give way. (3) The operation lifts up the uterus. If the vulval orifice is very large there

may still be a protrusion of the vaginal mucous membrane. It is well, therefore, to precede ventral fixation in women past child bearing by posterior colporrhaphy. (4) It is said to cause difficulty in labor, should the patient become pregnant. It does not always do so; and in many cases reported as illustrating such difficulty, the ventral fixation was not the cause of the difficulty. Ventral fixation after colporrhaphy, if the result be permanent, relieves the patient of any necessity for the continual readjustment of a pessary, and lifts the uterus up effectually. Ventral fixation is not advised in cases in which the womb can be comfortably kept up by a pessary."

SURGERY.

1. *Inflammation* is the name given to the succession of changes occurring in a part after an injury, provided the injury does not at once destroy its vitality.

Septicemia is an acute surgical infection caused by the absorption and development of bacteria in the blood of the patient.

Pyemia is an acute surgical infection caused by the diffusion of septic emboli throughout the circulation; metastatic abscesses are thus produced. *The organs most prone to pyemia* are the lungs, kidneys, spleen, liver, brain, and large joints.

2. The term denoting control of hemorrhage is *hemostasis. The methods of controlling hemorrhage* are: Pressure, forced flexion, forceps, clamps, torsion, ligature, cold, heat, cautery, elevation, styptics, suprarenal extract, ergot.

3. The popliteal artery should be ligatured and the dislocation reduced. The leg must then be carefully observed for some time, and if loss of vitality of the limb becomes evident amputation above the knee will be necessary.

4. ACUTE SUPPURATIVE OSTEOMYELITIS. "*Causes.*—The general vitality is lowered, and there is some focus of ulceration in the mouth or throat, by which organisms enter and circulate in the blood. All that is now necessary is that some part of a bone should have its vitality depressed by a blow, strain, or exposure to cold, and the organisms then attack it. The bacteria most commonly found are the staphylococci, but streptococci are present occasionally. The disease usually begins in the new growing bone at the end of the diaphysis, rarely in the epiphysis. The lower ends of the femur and radius, the upper ends of the tibia and humerus, are the commonest seats.

"*Symptoms.*—The disease begins with a rigor, high temperature, and severe pain. The part becomes swollen, infiltrated, and congested, with distended veins over it. The pulse is rapid and small and the tongue dry, and delirium soon comes on. It should be distinguished from acute rheumatism by the fact that the interarticular and not the articular region is affected. Fluctuation can be detected if the bone be superficial, or the abscess may burst on the surface. The bone is then found to be bare over the extent of the abscess cavity. When the bone is deeply seated or the disease confined to the medulla, the swelling is later in evidence, but the pain and toxemia are very severe, and the child may die from this before local signs show themselves. When the epiphysis is attacked, septic arthritis often quickly follows, and a loose flail joint may result.

"*Treatment* must be very prompt. A free incision must be made through the periosteum and the pus evacuated. In any case, whether pus is found or not, the surface of bone must be gouged away to expose the medulla freely, and any gangrenous tissue scraped out. The cavity must then be washed out and freely drained. The wound in the soft structures is not closed in any part. If symptoms of pyemia occur, it may be necessary to amputate the limb through the joint or bone above, so as to cut off the source of emboli. When a large portion of or the whole diaphysis is necrosed, there are two courses; either to cut short the disease by removing the dead portion at once, or to leave the sequestrum to stimulate the formation of an involucrum. Where there is a single bone, as in the arm and thigh, the sequestrum is left; where there is a double set of bones, as in the forearm and leg, the sequestrum is removed at once. Celluloid, zinc, and ivory rods have been inserted to stimulate osteogenesis. In most cases it is doubtful how much bone is actually dead, so that it is better to open up the cloacæ in the newly formed involucrum to remove the sequestrum. The cavity heals by granulation."—(*Aids to Surgery.*)

It is to be *diagnosed* from (1) *Rheumatism*, in which more than one joint is affected and the tenderness is *in* the joint, and not *near* it. (2) *Tuberculous arthritis*, in which the onset is slow and the trouble starts in the epiphysis rather than in the diaphysis. (3) *Cellulitis*, in which the bone and periosteum are not affected, and in which there is always a wound.

5. *Shock* is the name given to a sudden and general depression of the vital powers due to some strong stimulation (such as injury or emotion) acting on the vital centers in the medulla, and producing vasomotor paralysis.

Treatment of shock: Place the patient in the recumbent position, with the head low, apply warmth to the body, administer a stimulant and give a hot saline infusion; morphine hyperdermically, may be necessary for the relief of pain. Adrenalin solution is administered into the arterial system.

In surgical operations *shock may be largely prevented* by reassuring nervous patients, keeping the patient warm, the avoidance of the excessive catharsis and semi-starvation that often prevail before operations, the administration of strychnine and atropine before operation, the avoidance of delay and undue handling of parts during the operation, prompt checking of hemorrhage, and by using the utmost gentleness.

6. "In the treatment of compound fractures the main object is to render the wound aseptic and to give efficient exit to the discharges. For this purpose the patient should in all cases be anesthetized, the limb shaved, and thoroughly purified, and the wound enlarged and thoroughly washed out with some reliable antiseptic. It may be advisable to excise torn and dirty fragments of skin, muscle, and tendon, especially when dirt has been ground into them. Loose fragments of bone are removed and portions denuded of their periosteum may be taken away lest necrosis should ensue; where fragments retain any considerable connection with the soft parts they may be left without fear. When a sharp end of one of the fragments is protruding through a small opening in the skin it is first purified thoroughly before attempting its reduction and then replaced after enlarging the wound in the skin, or a portion sawn off. Hemorrhage is dealt with in the usual way, and the fragments are placed as nearly as possible in their normal position. If the fragments can be brought accurately into position it is well to fix them by some mechanical appliance; but where the ends of the bone are much comminuted the small portions must be arranged in position as well as possible, and no attempt made to wire them. A good-sized drainage tube is inserted, and, if need be, counteropenings are made; the external wound is closed or not, according to circumstances, and dressed, and suitable splints are then applied. Under such a régime the majority of cases do well. Immovable apparatus may be used after a time, windows being left in the plaster casing to allow wounds to be dressed."—(Rose and Carless' *Manual of Surgery.*)

7. *Ankylosis* is the condition in which the mobility of a joint is restricted or abolished. *True ankylosis* is caused by intra-articular lesions; *false*, by extra-articular lesions. The *true* ankylosis may be *bony* or *fibrous*. Ankylosis is also said to be *complete* or *incomplete*.

In bony ankylosis of the knee joint, if in false position, resection of a wedge-shaped piece of bone is necessary to make the limb straight. This is followed by extension, massage, and passive movement.

8. In *duodenal ulcer* there will be pain in the right hypochondriac region occurring about 3 hours after meals; intestinal hemorrhages which produce tarry or red stools; and anemia.

In *cholecystitis*, the pain is in the right hypochondriac or epigastric region, and occurs in paroxyms and without reference to time of eating; nausea, vomiting and jaundice may be present; constipation is common; and there is generally severe prostration.

9. ILEUS. *Varieties:*—(1) *Strangulation*, due to bands or adhesions or apertures; (2) *Volvulus*, due to twists on the axis of the mesentery or bowel; (3) *Intussusception*, due to excessive mobility and irritability of the intestine; (4) *Stricture*, due to cancer or scar tissue; (5) *Obstruction* by tumors, foreign bodies, fecal accumulation, or following an operation; the latter may be due to paralysis of the bowel or diminished peristalsis.

10. STONE IN THE URETER. *Symptoms:*—Severe colic, with pain radiating along the ureter; tenderness over the ureter; hematuria; the stone may be felt through rectum or vagina; a skiagram may show the stone; ureteral catheterization through the cystoscope may allow of the stone being touched by the catheter, and a waxed tip may receive a scratched impression.

It is *diagnosed* from *cystitis* (in this the urine is

alkaline, and pus is found at the beginning or end of urination); from *tuberculosis of bladder* (in this there are tubercle bacilli in urine, frequent urination, and the symptoms are not relieved by rest); from *prolapsed inflamed ovary* (the ovary is further from the vaginal wall, and the stone is felt in the antero lateral fornix). *Treatment:*—Except when anuria is present, observe the case to see if the stone is fixed or moving; if it is moving, allow time for it to pass into the bladder. If it is impacted near the kidney, attempt to push it back and remove it through pelvis of kidney; failing this, incise ureter and remove it, and then suture ureter. If impacted lower down, it should be removed by lumbar or sacral incision. In the renal colic, morphine, with hot fomentations is given. In case of anuria, nephrolithotomy is indicated.

HYGIENE.

1. *Four points to prevent acquiring or imparting tuberculosis:* (1) Compulsory notification of the disease; (2) prohibition of spitting except in proper receptacles, the sputum should be burnt or disinfected; (3) proper disinfection of houses or rooms occupied by tuberculous persons; (4) proper sanitary supervision of dairies, farms, cattle, milkshops, and workshops.

2. *The principal means of preventing the spread of contagious diseases in schools* are: Regular and efficient inspection by physicians; prompt exclusion and isolation of anyone suffering from a contagious disease, or coming from a house where such disease is; compulsory notification of all infectious and contagious diseases; individual towels, drinking vessls, and other implements; children who have had a contagious or infectious disease or who have come from a house where such disease prevailed should not be readmitted to school until sufficient time has elapsed since the occurrence of the last case to insure safety.

3. By the *hygiene of pregnancy* is meant the care which should be observed by the pregnant woman for the preservation of health and strength both of herself and of the fetus. The pregnant woman should take moderate exercise in the open air; in the last month massage may take the place of exercise. Daily bathing in tepid water, care of the teeth, regularity of the bowels, ample sleep in a well-ventilated room, plenty (but not too much) of simple, nourishing and easily digested food, at regular hours, clothing not too tight, especially about the abdomen and breasts; attention to the nipples, regular examination of the urine, and the restriction of marital relations are the main points to which advice should be directed.

4. *Prophylaxis of filth diseases* consists in the prevention of the ingress and accumulation of dirt, proper methods of removal by cleaning, and of destruction by burning; by having proper, tight receptacles for waste matter; by having proper plumbing and water supply; by proper ventilation of and sunlight in living and sleeping rooms; by not keeping domestic animals in the house, and by keeping such animals clean; by keeping out rats, mice, flies, mosquitoes and other insects as much as possible, and by personal cleanliness.

5. The *dangers from the housefly* are: Transmission of diseases, such as typhoid, tuberculosis, cholera, dysentery, diarrhea, anterior poliomyelitis, and possibly other diseases. The *mosquito* may transmit malaria, yellow fever, dengue, and filariasis.

To exterminate flies: "Since flies breed only in filth, the first thing to do is to render it impossible for the fly to reach any of the accumulations unavoidable around habitations. This is done: (1) By destroying filth wherever found. (2) By rendering it distasteful or poisonous to flies or their larvæ by the use of lime, kerosene, oil of pennyroyal or cresol. (3) By excluding light from the receptacle or by screens which the flies cannot pass. The most difficult part of an anti-fly campaign is teaching the people to dispose of their garbage properly. No amount of screening, trapping or poisoning will make up for careless disposal of filth and waste. All such materials must be promptly destroyed or buried. If a really good suspension of milk of lime (calcium hydrate) is mixed with the garbage or refuse, the eggs and pupæ or maggots of the fly are at once destroyed, but it must be made to come in contact with the eggs or maggots to do any good. Kerosene oil is more effective, but more expensive. Where crude oil or low grade distillates are procurable, the expense is much lessened. Oil of pennyroyal, in the proportion of 1 ounce to 1 quart of kerosene, is very distasteful to the adult fly, as well as fatal to the young, and a small quantity sprinkled around the garbage can is sufficient to keep away all flies. The greatest drawback is the expense. Cresol is not expensive, and may be used freely in 2 per cent. emulsion. Privy vaults, manure bins, and similar places must be made and kept perfectly dark. Screens must be made automatically self-closing, otherwise they are sure to be left open and to fail of their object."—(Gardner and Simond's *Practical Sanitation*). Fly poisons, flytraps and fly papers may also be used.

"*The most efficient way of getting rid of mosquitoes* is to make it impossible for them to breed. The eggs of a mosquito are laid in water, and water is absolutely necessary for the larval and pupal stages, which must be passed through before the adult mosquito is produced. Fish destroy developing mosquitoes and large sheets of water are too rough for them; so mosquitoes must have, for breeding, rather small collections of fresh water free from fish. Mosquitoes will soon disappear from a locality if all such collections of water within a quarter of a mile of it are filled up, drained, or covered with a film of coal oil so as to make it impossible for the mosquitoes to breed in them. Those who live in a malarious district should protect themselves from mosquito bites by the careful use of mosquito netting."—(Marshall's *Microbiology.*)

6. *The chief sources of contamination of drinking water* are: Sewage, including not only solid and liquid excreta, but also house water and waste water; manufacturing refuse, such as from dye works, bleaching works, tanneries, and numerous other industrial places; improper storage or service of water.

Drinking water may be purified by: Distillation, boiling, filtration, precipitation, and various chemical methods.

7. *Diseases specially liable to be conveyed by the ingestion of milk:* Tuberculosis, typhoid fever, scarlet fever, diphtheria, tonsilitis, cholera, and gastrointestinal disorders.

8. *Diseases due to microorganisms: Typhoid*, transmitted by food, water, milk, fingers, flies, and "carriers"; *dysentery*, transmitted by water, milk, vegetables, direct contact with patient and his discharges, flies; *cholera*, transmitted by food, water, and flies; *smallpox*, method of transmission is not known, possibly by air, flies, mosquitoes; *scarlet fever*, transmitted by secretions from nose, throat, and ear (suppurating), and scales from skin; *measles*, transmitted by direct contagion, fomites; *diphtheria*, transmitted by infected articles, "carriers," milk, fomites, domestic animals, secretions from throat or nose or ear; *influenza*, transmitted by "carriers," sputum; *mumps*, transmitted by contact; *plague*, transmitted by the flea, rats, squirrels, marmot; *Malta fever*, transmitted by milk of goat and possibly by biting insects; *anthrax*, transmitted by animals, wool, skin, rags; *glanders* and *farcy*, transmitted by inoculation; *foot and mouth disease*, transmitted by secretions of infected animals, and milk, butter, and cheese made from milk of such animals; *hydrophobia*, transmitted by saliva and bite of dog or wolf; *yellow fever*, transmitted by Stegomyia mosquito; *malaria*, transmitted by Anopheles mosquito; *dengue*, transmitted by Culex mosquito; *pellagra*, perhaps transmitted by Simulium (sand-fly); *erysipelas*, transmitted by inoculation; *tetanus*, transmitted by inoculation; *tuberculosis*, transmitted by inoculation, inhalation and ingestion; *leprosy*, transmitted by inoculation, contagion with secretions; *typhus*, transmitted by body lice and bedbug; *relapsing fever*, transmitted by bites of insects; *kala azar*, transmitted by bite of bedbug; *anterior poliomyelitis*, transmitted by secretions and flies; *cerebrospinal meningitis*, transmitted by nasal secretions and "carriers"; *syphilis*, transmitted by sexual contact, kissing, instruments, and inoculation; *gonorrhea*, transmitted by sexual contact; fingers or towels may also convey the virus.

9. The patient must be isolated; no one but the physician and nurse must enter the room; the physician should put on a large washable gown when he goes in and remove it on leaving, at the same time washing his hands in a disinfectant; the nurse, when she leaves the sick room, should also remove her clothes and put on others, at the same time disinfecting herself. At the termination of the disease everything should be disinfected: toys and books, etc., are better burned.

10. *Healthy* sleep is more apt to occur when the person is healthy and of correct habits; bodily comfort, mental repose, sufficient warmth, proper ventilation, a slight amount of fatigue, perfect quiet, and a comfortable bed are more or less necessary. Sometimes, in addition to the above, an evening walk, a warm bath at bedtime, and a light repast before retiring may be necessary.

ANIMAL EXPERIMENTS UPON THE ACQUIREMENT OF ACTIVE IMMUNITY BY TREATMENT WITH VON RUCK'S VACCINE AGAINST TUBERCULOSIS.

BY FRANK J. CLEMENGER, M.D.,

ASHEVILLE, N. C.

FORMERLY ASSISTANT, IMMUNIZATION DEPARTMENT, ST. MARY'S HOSPITAL;

AND

F. C. MARTLEY, M.A., M.D. (CAMBRIDGE),

LONDON.

INSTRUCTOR AND ASSISTANT, IMMUNIZATION DEPARTMENT, ST. MARY'S HOSPITAL.

(From the Laboratory of the Department for Therapeutic Immunization, St. Mary's Hospital; London, W., England.)

THE following experiments were undertaken for the purpose of independent observations in respect to the immunizing power of a specific vaccine made from extractives of the tubercle bacillus, as prepared and described by Dr. Karl von Ruck[1] of Asheville, N. C., at whose request one of the authors (F. J. C.) applied to Sir Almroth E. Wright, his former chief, for his consent to have the work done under his direction in his laboratory at St. Mary's Hospital in London. This request being granted by Sir Almroth Wright, arrangements were made accordingly.

In order to expedite the necessary studies, Dr. von Ruck supplied thirty-six guinea-pigs which had been immunized in his laboratory, to be taken to London. Through an unfortunate accident, thirty-two of the animals were drowned on shipboard. In fifteen of the autopsies, the animals showed lesions to which Dr. von Ruck had called the attention of one of us, as seriously interfering with his own experiments, which he then considered as spontaneous tuberculosis. Sections from tissues of two of these animals showed acid-fast bacilli. The four remaining animals were excluded from our experiments.

It was not intended to be within the scope of these experiments to undertake any work with the idea of establishing proof of the clinical value of this vaccine; but the interim caused by the necessity of immunizing a new lot of animals, was utilized for treating a few clinical cases selected by Sir Almroth Wright with this end in view. Realizing the long period of time which would be required to study a comparative series of cases under treatment with Tuberculin BE in routine use in the clinic of the Department at St. Mary's Hospital, Sir Almroth decided to select only cases for treatment with this vaccine, which had failed to show improvement under treatment with Tuberculin BE, and to note any changes that might become manifest through its influence.

Eight cases were assigned for this purpose, being of the type predominating in this clinic, namely six cases of lymph gland affections characterized by chronic sclerotic lesions, in which the enlarged glands varied in size from masses one to four inches in diameter, and two cases of lupus of long standing, one of which had existed for fifteen years and involved nearly all parts of the body; the second case had developed upon scar tissue forming after the removal of tuberculous glands from the neck; the lesions covered a patch one by one and one-half inches in size.

These cases were treated for three months with varying doses administered subcutaneously and, in some instances, intravenously. At the end of that time the clinical experiments were given up on account of the necessity of proceeding with the experiments upon animals. During the course of the treatment, forty-eight observations were made to ascertain the relation between the opsonic contents and the specific precipitins of the sera of these patients; but no uniformity could be established in their inverse proportions, as had been observed by Dr. von Ruck.[2]

In the course of treatment of these cases no permanent changes could be noted in the local lesions; but in four out of six cases of the glandular type, an improvement became manifest in the general condition of the patients, which suggests that the treatment had been beneficial. The other two of the glandular cases had presented no general symptoms and, from the fact that 1 c.c. of the vaccine was administered intravenously, without causing any reaction, it is possible that the lesions were not tuberculous.

The extensive case of lupus had been treated with other specific products for several years, during which periods of improvement and relapses had been noted; consequently no conclusion could be drawn when the treatment was discontinued. In the other, less extensive case, while presenting no definite changes in the local lesions, such a remarkable general improvement occurred that the change was noticeable to any one.

Considering the fact that all these cases which had been assigned, were of a character which implies a minimum circulation in the affected tissue, it is possible that, *no matter how much immune substances might be elaborated in response to a given vaccine, an influence upon the local lesions could hardly be expected by this means alone.*

Animal Experiments.—Great difficulties were encountered in obtaining guinea-pigs free from pseudotuberculosis and, as will be shown later, a large number of the animals used in the experiments were found to be affected with various types thereof.

In our search for normal animals suitable for our experiments, a dealer was found who claimed that

he had never had any infection among his animals, either acute or chronic. From his stock, 104 male guinea-pigs were chosen, and their active immunization was undertaken by the subcutaneous administration of successively increasing doses of the vaccine. A number of these animals died, especially during the early part of their treatment, and on autopsy they were found to present lesions which resembled tuberculosis. Captain Stewart R. Douglas, I.M.S., assistant director of the department, was consulted and suggested that we were dealing with a chronic form of pseudotuberculosis. In our further investigations we isolated a short coccobacillus from some of the lesions, and also a Gram-negative bacillus whic hseemed to be identical with the *Bacillus pseudotuberculosis rodentium* described by Pfeiffer.

It was decided, however, to proceed with the immunization of the remaining animals, because it was doubtful whether a perfectly reliable source of animals could be found. After a certain number of doses of the vaccine had been administered, the sera of the animals were tested by a technique of complement-fixation described by Dr. von Ruck.[3] At this time there remained fifty-one animals of the original lot. In six of these, Dr. von Ruck's criterion in complement-fixation was reached with antigens supplied by him. In the remainder the results were only partial or negative.*

It appeared after many attempts, that the binding power of the antigens for complement was very variable and unstable, especially in the presence of hemolytic amboceptor of high titer, and it became necessary to employ amboceptors of low titer, in order to obtain any results at all. The hemolytic system used was rabbit hemolysin for calf-cells, with either guinea-pig or rabbit serum for complement. The rabbit complement frequently proved so weak and variable, that it had to be abandoned, and the partial results that were obtained occurred when guinea-pig complement had been employed.

To eliminate the possible adverse influence of pseudotuberculosis, in the sera used for complement, a further search for normal guinea-pigs was undertaken. A lot was purchased from a guinea-pig fancier who bred his animals exclusively for purposes of exhibition. These animals were young and, from all outward appearances, they were perfectly healthy. A point was made to autopsy, with great care, each of the guinea-pigs of this lot, that had been killed for the purpose of securing fresh serum for complement, and pseudotuberculous lesions were found in every one of them, over thirty in number. We are not prepared to express an opinion on the exact relation of sera from animals affected with pseudotuberculosis upon the variability and unreliability in complement-fixation tests. We have thought of non-specific fixation, or of deviation of complement through the presence of a large amount of amboceptor for the organisms of pseudotuberculosis; but we did not have the time and opportunity to study the subject critically.

The amazing point about these infections with pseudotuberculosis is the large amount of tissue in vital organs, which can be involved in the local processes and yet permit the animals to live in apparent health. The assumption of a certain degree of an acquired immunity against the bacteria causing the pseudotuberculosis, which prevents generalization through the blood, possibly may account for these observations and also for the earlier deaths which took place after the administration of anti-tuberculosis vaccine, or after infection with tubercle bacilli, which would then cause a disturbance of this acquired immunity. In any case, the presence of an infectious disease, which in its course has caused such extensive involvement of vital organs, may well be considered a hopeless barrier to the successful immunization of the affected animal against tuberculosis or against any other infection.*

Bactericidal Experiments.—Our bactericidal experiments will be considered first, because they preceded the infection of treated animals. Their object was to demonstrate a difference in the germicidal action of human sera, accordingly as they were taken before or after the administration of the vaccine. If such a difference could be clearly established in a sufficiently large number of cases in favor of the sera taken after one or more doses of the vaccine, such a result would have to be accepted as conclusive.

For preliminary experiments, the sera of nine persons were obtained, who had not before been treated with the von Ruck vaccine or with any other product of the tubercle bacillus.

The technique for these and for the bactericidal experiments with sera taken after vaccination, was as follows: Two drops of the person's serum were mixed with two drops of an emulsion of living tubercle bacilli, containing 0.01 mgr. of the bacilli. This mixture was agitated in a test-tube and then placed in an incubator at 37° C. over night. The mixture was then injected subcutaneously into a guinea-pig. For the infection of control animals, an equal amount of normal serum was substituted for the human serum in one group, and normal salt solution in another group of animals, all control test-tubes being otherwise treated exactly like those intended for the principals.†

The results of these experiments are given in Table I.

Apparently the human serum had a slight inhibitory effect, increasing the average duration of life.

It is readily seen that the purpose of the experiment has been accomplished in the above group. Guinea-pig No. 1 (Dick) shows some modification of virulence, and justly so. The serum had given positive results in the complement-fixation test, indicating that its donor had developed a fair amount of immunity to the tubercle bacillus. At a later date

*The antigens were four in number: (1) a fat-free emulsion of tubercle bacilli; (2) a lipoid, neutral in reaction; (3) a fatty acid; (4) a water-soluble protein. The double guide indicating successful resistance to infection, which was conditioned by Dr. von Ruck as essential, was that the sera should give complete fixation in serum dilutions of 1:8 with all antigens; and that 0.2 c.c. of the active serum should cause marked morphological changes upon 0.01 mgr. of virulent tubercle bacilli of human origin, *in vitro*, after incubation for twenty-four hours at 37° C.

*Aside from the disappointing and inseparable complications of infection with pseudotuberculosis in our experiments, the possibility of error in utilizing guinea-pigs for diagnostic experiments became manifest in the course of our studies. The inoculation of a guinea-pig with suspected fluids or tissues may lead to serious error, unless the results are studied and controlled in a more critical manner than is the usual custom. Our observations also raise the question of the reliability of some of the experiments in tuberculosis recorded in literature, in which such critical studies were omitted.

†All emulsions used in these experiments were made by Dr. Achard of Dr. v. Ruck's staff, who placed them in the hands of Dr. Parry Morgan of the staff of the Department. Dr. Morgan put up the serum and bacterial mixtures in this and in subsequent experiments and witnessed their use for the infections.

he responded to the vaccine with a sharp reaction and manifested a decided improvement in his physical condition during the weeks following. Excluding guinea-pigs Nos. 6 and 14, on account of the short time they lived after infection, it will be found that 100 per cent. of the sera which are left show no modifying action upon the virulence, except in the duration of life; or, if the result in G. P. No. 1 is interpreted as manifesting a modifying influence, 85.7 per cent. will be left in which no modifying action upon the virulence was evident.

Table 1—Animal Experiments with Human Sera Taken Before Vaccination

Name	Animal No.	Death	Lived, Days	Autopsy
Hayman	15	Found dead in cage	103	Disseminated lymph gland tbc.
Storrer	13	Found dead in cage	109	Generalized tbc.
Francis	6	Killed	29	Excluded, having been killed through error.
Duff	14	Found dead in cage	1	Excluded on account of early death.
Hardy	5	Killed	117	Disseminated lymph gland tbc.
Menereau	33	Killed.	117	Generalized tbc.
Henry	2	Killed.	117	Disseminated lymph gland tbc.
Edwards	4	Found dead in cage.	102	Generalized tbc.
Dick	1	Found dead in cage.	103	Tbc. of regional lymph glands.
Controls.				
Normal salt.	9	Found dead in cage.	80	Generalized tuberculosis.
Normal salt.	10	Found dead in cage.	80	Generalized tuberculosis.
Normal salt.	11	Found dead in cage.	80	Generalized tuberculosis.
Normal salt.	12	Found dead in cage.	109	Disseminated lymph gland tuberculosis.
G.P. Serum.	8	Killed.	117	Disseminated lymph gland tuberculosis.
G.P.-Serum.	16	Found dead in cage.	80	Generalized tuberculosis.
G.P.-Serum.	17	Found dead in cage.	30	Apparently pseudotuberculosis.*
G.P.-Serum.	18	Found dead in cage.	2	Apparently pseudotuberculosis.*
G.P.-Serum.	7	Killed	101	Tuberculosis of regional lymph glands.

*Serum controls Nos. 17 and 18 are excluded on account of early death.

After these infections had been made, the individuals who had supplied the sera for this group were given each one dose of the vaccine. Excepting one infant (Duff) and a child (Francis), all reacted to its administration, the reactions being attended by fever. The sera of these persons were tested after five days. Bacteriolysis *in vitro*, of tubercle bacilli, could not be demonstrated in any of them* and the same is true for the sera obtained from animals which had been treated with the vaccine, in the subsequent experiments. In the latter sera an obstacle to the demonstration of bacteriolysis was encountered also in the gross contamination of the specimens, which was unavoidable on account of having to bleed the animals from the ear.

The difficulties in the complement-fixation test, which we encountered, have already been described. It was agreed, because of these difficulties, to take specimens of serum from the vaccinated individuals, on three successive days, hoping that a positive serum would be secured on one or more of these three occasions. Two drops of the respective serum were then placed in a sterile test-tube, and 0.01 mgr. of tubercle bacilli in emulsion added, the tubes being placed in the incubator over night. The content of each individual tube was then used for the subcutaneous infection of a guinea-pig. Control experiments were made in a certain number of animals with the contents of tubes containing a like quantity of tubercle bacilli, while the immune human sera were replaced by normal human serum or by normal salt solution.* The results of the bactericidal experiments with sera taken after vaccination with a single dose in four adults, two children and one infant, and with sera from two other adults who had received two doses of the vaccine before the present studies were undertaken, are given below.†

Bactericidal Experiments with Human Sera taken after the Administration of Vaccine.

Adults. Dick. Serum taken vii/20/14. G.P. No. 6, infected subcutaneously in left axilla; weight 500 grams. Killed 124 days after infection; weight 530 grams.

Autopsy: Infection site open lesion. Left axillary glands 3x3 mm., caseous; 3x4 mm., caseous; right axillary gland 2x3 mm., caseous.

Liver, 1½ times normal size; several patches of fibrocaseous degeneration.

Mesenteric glands from a caseous mass, 10x3 mm.

Spleen, 8 times normal size; a mass of fibrocaseous degeneration.

An omental gland under spleen, 2x3 mm., fibrous.

Lungs, numerous greenish tubercles; some caseation.

Mass of bronchial glands, 6x4 mm., caseous.

Smears made for tubercle bacillus: positive, left axillary gland; mesenteric gland; spleen; bronchial glands; retrosternal gland; negative lung and liver.

Cultures for microorganisms of pseudotuberculosis, positive for liver; negative for spleen and lung. *Generalized Tuberculosis.*

Dick. Serum taken vii/21/14. G.P. No. 16; infected subcutaneously in left axilla; weight 330 grams. Killed 122 days after infection; weight 465 grams.

Autopsy: Infection site not found. Spleen normal size, mottled. Mesenteric gland 1x1 mm. Lungs slightly mottled.

Smears from spleen and mesenteric gland negative. *No Tuberculosis.*

Dick. Serum taken vii/21/14. G. P. No. 23. Infected subcutaneously in left axilla; weight 345 grams. Died 38 days after infection; weight 430 grams.

Autopsy: Infection site, nothing abnormal noticed except an axillary gland 3x5 mm., normal in consistency. Abdomen: Exudation and free feces found in peritoneal cavity; quantity 2 c.c. Mesentery, injected at gastroenteric margin. Kidneys, normal; left suprarenal injected. Spleen, size normal, with dark red borders; otherwise normal. Testicles normal. Retroperitoneal glands normal. Liver normal. Diaphragm injected. Lungs, normal.

Smears: No tubercle bacilli found in smears from infection site and from peritoneal exudate.

Cause of death, probably injury. *No Tuberculosis.* Excluded on account of early death.

Achard. Serum taken vii/20/14. G.P. No. 8. Infected subcutaneously in left axilla; weight 520 grams. Killed 122 days after infection; weight 590 grams.

Autopsy: Left axillary glands 3x2 and 2x2 mm., caseous. Mesenteric glands 2x2 mm., fibrous. Liver: normal size; many small miliary patches scattered throughout central and left lobe. Two large areas of miliaries on border of left and central lobes, 3x2 mm. Spleen: Nine fibrocaseous nodules. Lungs: 8 or 10 small gray tubercles scattered through lung.

Smears from left axillary glands, mesenteric glands, liver, spleen, lung, all negative as to T.B.

Cultures for organisms of pseudotuberculosis, from liver, spleen, lung, all negative. *No Tuberculosis.*

Achard. Serum taken vii/21/14. G.P. No. 12. Infected subcutaneously in left axilla; weight 365 grams. Killed 122 days after infection; weight 560 grams.

Autopsy: Infection point not found. Mesenteric lymph gland or fat, 2x1 mm. Liver apparently normal. Spleen normal, dark. Lungs normal except for small patch of consolidation in middle right lobe.

*When decolorization of slides, made for the purpose of demonstrating bacteriolysis *in vitro* of tubercle bacilli, was done with 25 per cent. sulphuric acid, no lysis was demonstrated. Slides decolorized with lesser percentages of acid were not accepted by Captain Douglas, on account of possible retention of stain by contaminating bacteria.

*For this group of principals and controls still another source of guinea-pigs had been utilized. Two of the animals were killed when first received; they were found entirely normal on autopsy, and we were fortunate in finding very little pseudotuberculosis among the rest of these animals. It was a matter of great disappointment that it was not possible to obtain enough animals from this source for all our subsequent experiments.

†Several of the persons who had furnished serum for the preliminary experiments (see Table I.) were not included in the present tests, because it was not practicable to obtain specimens of their blood.

Smears for mesenteric gland or fat, from liver, spleen, lungs, negative as to tubercle bacilli. *No Tuberculosis.*

ACHARD. Serum taken vii/22/14. G.P. No. 21. Infected subcutaneously in left axilla; weight 405 grams. Killed 123 days after infection; weight 600 grams.

Autopsy: Infection point not found. Spleen mottled. Smears from spleen negative as to tubercle bacilli. *No Tuberculosis.*

STORER. Serum taken vii/20/14. G.P. No. 7. Infected subcutaneously in left axilla; weight 480 grams. Killed 122 days after infection, weight 480 grams.

Autopsy: Left axillary lymph gland 3x2 mm., caseous; another 2x2 mm. normal. Spleen 3 whitish nodules, 2x1 mm. Lungs normal except for 2 small grayish spots, ½x1 mm. Smears from left axillary gland, tubercle bacilli found; from spleen and lungs, no tubercle found. Cultures for organisms of pseudotuberculosis, from spleen and lungs, negative. *Tubercle bacilli at Infection Point.*

STORER. Serum taken vii/21/14. G.P. No. 14. Infected subcutaneously in left axilla; weight 350 grams. Killed 122 days after infection; weight 510 grams.

Autopsy: Infection point not found. Mesenteric gland, 1x1 mm. normal. Liver normal except for 1 small whitish patch on outer border of left lobe, and 1 on inner border of left lobe. Spleen mottled. Lungs some intense mottling. Smears from mesenteric glands, liver, and spleen negative as to tubercle bacilli. Cultures for organisms of pseudotuberculosis from liver and lung, negative. *No Tuberculosis.*

STORER. Serum taken vii/22/14. G.P. No. 19. Infected subcutaneously in left axilla, weight 340 grams. Killed 123 days after infection; weight 430 grams.

Autopsy: Infection point not found. Liver normal. Spleen normal, dark. Lungs normal, a little mottled. Smears from spleen no tubercle bacilli found. *No Tuberculosis.*

COLEBROOK. Serum taken vii/20/14. G.P. No. 4. Infected subcutaneously in left axilla; weight 510 grams. Died 119 days after infection; weight 370 grams.

Autopsy: Enormously distended bladder. Infection site: 2 lymph glands 4x3 mm., caseous. Spleen, 2 white patches, 4x2 mm. and 2x2 mm. Lungs intensely mottled; one small greenish surface, 1x1 mm. on posterior surface of lower left lobe; lower right lobe intensely congested.

Smears: Tubercle bacilli found in axillary lymph glands and spleen; none found in lung.

Culture for organisms of pseudotuberculosis from spleen, Gram-negative coccobacillus found; lung negative. *Generalized Tuberculosis.*

COLEBROOK. Serum taken vii/21/14. G.P. No. 13. Infected subcutaneously in left axilla; weight 415 grams. Killed 121 days after infection; weight 500 grams.

Autopsy: Infection point not found. Spleen normal, dark. Lungs slight anthracosis. Smears from spleen, no tubercle bacilli found. *No Tuberculosis.*

COLEBROOK. No serum available on vii/22/14.

HENRY. Serum taken vii/20/14. G.P. No 5. Infected subcutaneously in left axilla; weight 470 grams. Killed 123 days after infection; weight 560 grams.

Autopsy: Open lesion at infection site; caseous. Left axilla, lymph gland 2x1 mm., normal consistency. Spleen normal size and appearance, except a slight line across one end, 3 mm. long, whitish, suggesting scar tissue. Mesenteric glands 6 x 4 mm., fibrocaseous. Lung, 1 green spot, 1x1 mm., border of left upper lobe.

Smears: Infection site, axillary gland, spleen, mesentric gland, no tubercle bacilli found.

Cultures for organisms of pseudotuberculosis, from lungs negative. *No tuberculosis.*

HENRY. Serum taken vii/21/14. G.P. No. 17. Infected subcutaneously in left axilla; weight 450 grams. Died 119 days after infection; weight 420 grams.

Autopsy: Infection point not found. 1 mesenteric gland, ½x1 mm., apparently normal. Liver normal except for 2 minute whitish spots, ½x½ mm. Spleen normal, mottled. Lungs: Top of right lung, patch ½x2 mm., white; area of congestion in lower lobes (marked).

Smears: Mesenteric gland, liver, spleen, lung, no tubercle bacilli found.

Culture for organisms of pseudotuberculosis, from liver and lung, negative. *No tuberculosis.*

HENRY. Serum taken vii/22/14. G.P. No. 20. Infected subcutaneously in left axilla; weight 375 grams. Killed 121 days after infection; weight 480 grams.

Autopsy: Left axillary lymph gland 4x3 mm. Spleen slightly mottled.

Smears: Tubercle bacilli found in left axillary lymph gland; none found in spleen. *Regional lymph-gland tuberculosis.*

F. J. C. Serum taken vii/20/14. G.P. No. 2. Infected subcutaneously in left axilla; weight 450 grams. Died 119 days after infection; weight 330 grams.

Autopsy: Infection site, 2 lymph glands, 2x2 mm., caseous. Mesenteric gland, 1x½ mm., fibrous. Spleen normal in size; *2 fibrous nodules*, 2x2 and 1x½ mm. Liver normal except for 1 small whitish patch, 1x1 mm. Lungs intensely mottled; 1 small gray nodule at base of left lower lobe; 1 on lower border of upper lobe.

Smears: Mesenteric gland, spleen, axillary lymph gland, tubercle bacilli found. Lung, no tubercle bacilli.

Cultures for organisms of pseudotuberculosis, spleen and liver negative. Gram negative coccobacillus in lung. *Generalized Tuberculosis.*

F. J. C. Serum taken vii/21/14. G.P. No. 11. Infected subcutaneously in left axilla; weight 375 grams. Killed 121 days after infection; weight 495 grams.

Autopsy: Infection point not found. Spleen normal, dark. Lungs a little anthracosis. Smears: Spleen, no tubercle bacilli found. *No Tuberculosis.*

F. J. C. Serum taken vii/22/14. G.P. No. 24. Infected subcutaneously in left axilla; weight 340 grams. Killed 121 days after infection; weight 460 grams.

Autopsy: Infection point not found. Liver normal except 2 minute whitish spots, under surface of left lobe. Spleen normal size, mottled. Lungs, pneumonic patch, central portion of upper right lobe.

Smears: Liver, spleen, lungs, no tubercle bacilli found.

Culture for organisms of pseudotuberculosis: Liver and lungs negative. *No Tuberculosis.*

Children.

EDWARDS. Serum taken vii/20/14. G.P. No. 3. Infected subcutaneously in left axilla; weight 570 grams. Killed 123 days after infection; weight 625 grams.

Autopsy: Left axillary lymph gland 4x3 mm., caseous. Spleen normal size, mottled; whitish patch at tip 3 mm. Mesenteric gland 2x3 mm., fibrous. Lungs intensely congested; 1 minute greenish spot on lower left lobe.

Smears: Left axillary gland, tubercle bacilli found, spleen, mesenteric gland, lungs, no tubercle bacilli found.

Cultures for organisms of pseudotuberculosis: Spleen and lungs negative. *Regional Lymph Gland Tuberculosis.*

EDWARDS. No serum available vii/21/14.

EDWARDS. Serum taken vii/22/14. G.P. No. 22. Infected subcutaneously in left axilla; weight 370 grams. Killed 122 days after infection; weight 480 grams.

Autopsy: Infection point not found. Spleen normal, slightly mottled. Lungs slightly mottled. Smears: Spleen, no tubercle found. *No Tuberculosis.*

FRANCIS. Serum taken vii/20/14. G.P. No. 9. Infected subcutaneously in left axilla; weight 540 grams. Died 120 days after infection; weight 430 grams.

Autopsy: Infection point not found. One retroperitoneal lymph gland 1x2 mm., apparently normal. Liver normal except for a few whitish spots ½x½ mm. Spleen normal, mottled. Lungs intense congestion.

Smears: Retroperitoneal lymph gland, liver, spleen, no tubercle bacilli found.

Cultures for organisms of pseudotuberculosis: Liver and lungs negative. *No Tuberculosis.*

FRANCIS. Serum taken vii/21/14. G.P. No. 15. Infected subcutanously in left axilla; weight 500 grams. Killed 121 days after infection; weight 515 grams.

Autopsy: Infection point not found. Spleen normal, very blackish. Smears: Spleen, no tubercle bacilli found. *No Tuberculosis.*

FRANCIS. No serum available vii/22/14.

BABY DUFF (Infant). Serum taken vii/20/14. G.P. No. 1. Infected subcutaneously in left axilla; weight 490 grams. Killed 123 days after infection; weight 610 grams.

Autopsy: Infection point not found. Liver normal except for 1 minute spot, ½x½ mm., central lobe. Spleen dark mottled. Mesenteric gland 3x2 mm.

Smears: Spleen, mesenteric gland, liver, no tubercle bacilli found. *No Tuberculosis.*

BABY DUFF. Serum taken vii/21/14. G.P. No. 10. Infected subcutaneously in left axilla; weight 470 gms. Killed 121 days after infection; weight 565 grams.

Autopsy: Infection point not found. Spleen normal size, mottled. Lungs a little anthracosis. Smears: Spleen no tubercle bacilli found. *No Tuberculosis.*

Baby Duff. Serum taken vii/22/14. G.P. No. 18. Infected subcutaneously in left axilla; weight 365 gms. Killed 120 days after infection; weight 525 grams.

Autopsy: Left axillary lymph gland 2x1 mm., apparently normal. Liver normal except for 3 small whitish patches, ½x1 mm. Spleen normal, dark. Lungs mottled. irregular anthracosis.

Smears: Liver, spleen, lungs, left axillary lymph gland, no tubercle bacilli found.

Cultures for organisms of pseudotuberculosis: Liver, gram negative cocco-bacillus. *No Tuberculosis.*

Controls for Virulence.—Normal Salt Control. vii/20/14. G.P. No. 34. Infected subcutaneously in left axilla; weight 385 gms. Killed 121 days after infection; weight 540 grams.

Autopsy: Open wound at infection site. Left axilla, 2 glands, 2x3 mm., caseous; cervical gland, 3x4 mm., caseous; Mesenteric gland 6x6 mm., caseous. Liver a mass of small whitish patches. Spleen 3 times normal size, a mass of fibrocaseous areas. Lungs a mass of small tubercles. Mass of bronchial glands, 10x15 mm., caseous. Retrosternals 4x3 mm., caseous.

Smears: Mesenteric and retrosternal glands tubercle bacilli found, liver, spleen, lungs, axillary glands, no tubercle bacilli found.

Cultures for organisms of pseudotuberculosis: Liver, spleen, lungs, negative. *Disseminated Lymph Gland Tuberculosis.*

Normal Salt Control, vii/20/14. G.P. No. 33. Infected subcutaneously in left axilla; weight 335 gms. Died 117 days after infection; weight 355 grams.

Autopsy: Left axilla, 2 glands, 7x4 mm., caseous; right axilla, 1 gland, 2x3 mm., one 3x5 mm. Right inguinals, one 5x7 mm., one 2x3 mm., caseous. Left inguinals enlarged. Two cervicals 2x4 mm. Mesenteric gland 2x3 mm., caseous, one 3x5 mm. Retroperitoneal gland 1x1 mm., normal. Liver fibrocaseous masses, 2x2 to 4x7 mm., all lobes. Spleen 3 times normal; fibrocaseous masses throughout. Lungs a mass of tubercles, all lobes. Bronchial glands, mass 4x6 mm., fibrocaseous.

Smears: Infection point, mesenteric, inguinal and bronchial glands, liver, spleen, lungs, tubercle bacilli found.

Cultures for organisms of pseudotuberculosis: Liver and lungs negative; spleen, a Gram-positive coccus. *Generalized Tuberculosis.*

Normal Salt Control, vii/21/14. G.P. No. 30. Excluded on account of leaky syringe, losing part of contents.

Normal Salt Control, vii/21/14. G.P. No. 29. Infected subcutaneously in left axilla; weight 350 gms. Killed 120 days after infection; weight 530 grams.

Autopsy: Open lesion at infection site. Left axilla, mass of glands, 40x15 mm., caseous. Right axilla, gland 6x6 mm., caseous. Mesenteric mass of glands, 10x15 mm., caseous. Liver, central lobe several areas of fibrocaseous degeneration. Spleen four times normal; a mass of fibrocaseous nodules. Lungs, base shows number of small tubercles and fibrocaseous areas. Mass of bronchial glands, 12x8 mm., caseous.

Smears: Left axillary lymph glands and bronchial glands, tubercle bacilli found. Liver, mesenteric glands, spleen, lungs, no tubercle bacilli found.

Culture for organisms of pseudotuberculosis: Liver and spleen, negative. *Disseminated Lymph-Gland Tuberculosis.*

Normal Salt Control. vii/22/14. G. P. No. 26. Infected subcutaneously in left axilla; weight 370 grams. Died 58 days after infection; weight 490 grams.

Autopsy: Axillary glands 4 x 6 mm. caseous. Spleen, 5 areas 4 x 4 mm., caseous. Lungs, few white tubercles at base, right lobe: otherwise normal. Peritoneal exudate, 2 c.c., bloody. Left axillary gland, 2 x 2 mm. Retrosternal gland caseous.

Smears: Axillary and retrosternal glands, tubercle bacilli found. Peritoneal exudate, spleen, liver, lungs. No tubercle bacilli found. *Disseminated Lymph Gland Tuberculosis.*

Normal Salt Control. vii/22/14. G. P. No. 25. Infected subcutaneously in left axilla; weight 335 grams. Died 97 days after infection; weight 320 grams.

Autopsy: Left axilla, mass of glands, 10 x 5 mm. caseous. Gland below left ribs 10 x 20 mm. caseous. Left inguinal glands, 10 x 5 mm. caseous; 3 x 2 mm. caseous. Adhesions small intestine to parietal peritoneum; omentum adherent to stomach and spleen. Mesenteric gland, 3 x 2 mm. fibrous. Retroperitoneal, fibrocaseous gland, 3 x 5 mm., two 5 x 2 mm. fibrous. Intestines adherent to liver. Liver, under surface, several whitish patches up to 3 x 3 mm.; top surface all lobes similar. Spleen mass of whitish nodules up to 3 x 3 mm., twice normal size. Pancreas 2 x 11 mm. fibrocaseous. Peritoneal exudate 2 cc. serous. Lungs, upper lobes deeply congested; all lobes several (base) greenish patches 1 x 1 mm.; middle right lobe many greenish patches, 1 x 1 mm.; few on right lower lobe. Left lung covered with greenish patches, 1 x 1 mm. Mass of posterior mediastinal glands, 5 x 3 mm. caseous. Mass of anterior mediastinal glands, 10 x 15 mm. caseous.

Smears: Left axillary glands, gland on margin of ribs. Liver, pancreas, no tubercle bacilli found. Left inguinal, mesenteric, retroperitoneal, posterior mediastinal, retrosternal lymph glands, lungs, tubercle bacilli found.

Cultures for organisms of pseudotuberculosis. Liver: Gram-negative coccobacillus. Spleen negative. *Generalized Tuberculosis.*

Serum Controls.

Normal Human Serum. vii/20/14. G. P. No. 36. Infected subcutaneously in left axilla; weight 355 grams. Died 117 days after infection; weight 400 grams.

Autopsy: Open lesion at infection site. One cervical lymph gland 2 x 3 mm. caseous. Left axilla, mass 8 x 4 mm. caseous. Right axilla, 2 x 2 mm. fibrous. Omentum 3 tubercles, 2 x 1 mm. Mass of mesenteric glands, 3 x 4 mm. Liver full of white fibrocaseous patches. Spleen three times normal size; numerous fibrocaseous nodules. Lungs a mass of small grayish tubercles. Mass of bronichial glands, 6 x 8 mm. caseous.

Smears: Spleen, bronchial glands, left axillary glands, tubercle bacilli found. Liver and lungs, no tubercle bacilli found.

Cultures for organisms of pseudotuberculosis, liver, spleen, lungs, negative. *Generalized Tuberculosis.*

Normal Human Serum. vii/20/14. G. P. No. 35. Infected subcutaneously in left axilla; weight 360 grams. Died 112 days after infection; weight 360 grams.

Autopsy: Open lesion near infection site. Two left axillary glands 6 x 4 mm. caseous; right same, and one fibrous. Left inguinal 6 x 4 mm. caseous. Peritoneal exudate 2 cc. Omentum several small whitish tubercles. Mesenteric gland, 6 x 6 mm. caseous. Liver, mass of irregular whitish areas. Spleen mass of fibrocaseous nodules. Pleural exudate 2 cc. Lungs, mass of small, fibrocaseous tubercles. Left lower lobe, large fibrocaseous area, 2 x 3 mm. Mass of retrosternal glands. caseous. Mass of bronchial glands, 10 x 5 mm. caseous.

Smears: Right axillary, mesenteric glands, lungs, tubercle bacilli found. Liver, spleen, brochial glands, no tubercle bacilli found.

Cultures for organisms of pseudotuberculosis; liver and spleen, negative. *Generalized Tuberculosis.*

Normal Human Serum. vii/21/14. G. P. No. 32. Infected subcutaneously in left axilla; weight 375 grams. Killed 120 days after infection; weight 570 grams.

Autopsy: Left axilla, mass, 20 x 30 mm. caseous. Right axilla, 3 x 2 mm. normal in consistency. Right inguinals, 6 x 4 mm. fibrocaseous. In front of sternum, gland 4 x 6 mm. Cervicals 3 x 4 mm. Mesentery, mass 10 x 15 mm. caseous. Liver several small whitish areas. Spleen 3 times normal; a mass of fibrocaseous nodules. Lungs, base shows numerous small grayish tubercles. Retrosternal glands, two, 4x4 mm., caseous. Bronchial glands, mass 5x10 mm.

Smears: Mesenteric glands, tubercle bacilli found. Left axilla, liver, lungs, retrosternal gland, spleen, no tubercle bacilli found.

Cultures for organisms of pseudotuberculosis: Liver, spleen, negative. *Disseminated Lymph Gland Tuberculosis.*

Normal Human Serum. vii/21/14. G. P. No. 31. Infected subcutaneously in left axilla; weight 335 grams. Killed 120 days after infection; weight 540 grams.

Autopsy: Infection point not found. Mesenteric gland, 3x4 mm., fibrocaseous. Spleen normal, mottled. Lungs whitish nodule, 2x2 mm., in right upper lobe.

Smears: Mesenteric gland, spleen, lungs, no tubercle bacilli found.

Culture for organisms of pseudotuberculosis: Lung, Gram-positive thick bacillus. *No Tuberculosis.*

Normal Human Serum. vii/22/14. G. P. No. 28. Infected subcutaneously in left axilla; weight 340 grams. Killed 120 days after infection; weight 630 grams.

Autopsy: Infection point not found. Mesenteric

gland, ½x1 mm., apparently normal. Spleen normal, mottled. Lungs normal except for one small congested spot on left upper lobe.

Smears: Mesenteric gland, spleen, no tubercle bacilli found. *No Tuberculosis.*

Normal Human Serum. vii/22/14. G. P. No. 27. Infected subcutaneously in left axilla; weight 395 grams. Died 115 days after infection; weight 450 grams.

Autopsy: A few cervicals, 2x3 mm., fibrous. Axillæ, one on each side, fibrous. Peritoneum full of exudate, 20 cc. Liver, mass of fibrocaseous areas all lobes. Spleen 8 times normal size, a mass of fibrocaseous areas. Lungs intensely congested, full of small gray tubercles. Mass of bronchial glands, 20x15 mm., caseous.

Smears: Liver, lungs, bronchial glands, tubercle bacilli found. Spleen, no tubercle bacilli found.

Cultures for organisms of pseudotuberculosis: Liver and spleen, Gram-negative coccus. *Generalized Tuberculosis.*

Twenty-three human sera are to be considered in this experiment, and of this number, seven were without lesions, eight had slightly discolored patches or a questionable gland which proved to be of non-tuberculous nature, and two had lesions which can justly be interpreted as pseudotuberculous, since no tubercle bacilli could be discovered in them. Three proved to have generalized tuberculosis, while bacilli could be demonstrated only in the regional lymph glands of the remaining three. This summarizes a resistance to infection with tubercle bacilli in seventeen animals of this group. If we wish to exclude the two with pseudotuberculosis, we have fifteen animals which totally resisted infection.

The salt controls designed to show the virulence of these infections, all acquired tuberculosis, whereas of the normal-serum controls designed for comparison with the results obtained with immune sera, four showed tuberculosis and two did not acquire tuberculosis.

Our autopsies show that the sera from one of the vaccinated individuals had resisted infection on the three days, four on two out of the three days, and four on one of the three days on which the sera had been taken.

Active Immunization.—The treatment of the animals to be considered consisted in the subcutaneous administration of vaccine in doses of 1 to 5 milligrams, at intervals of about seven days, the doses being increased or repeated, not under five days, accordingly as they appeared to be well borne. The total number of doses varied from twelve to sixteen and averaged fourteen for all animals which outlived their treatment.

We have referred to the frequent deaths from pseudotuberculosis, which occurred during the treatment of the animals. We started with 104 guinea-pigs, and only 51 remained living and in good condition when we proceeded to test their sera with a view of determining their contents of specific amboceptors for the several antigens, and the degree of morphological changes upon virulent tubercle bacilli *in vitro*, with a view of selecting those of the animals for infection, which would comply with the standard heretofore mentioned as a guide.

We have stated the difficulties which we encountered in the complement fixation tests. After several attempts to overcome them, we had found only six sera in which the titer reached the requirements; in the sera of the other animals, the results were only partial or negative. But, inasmuch as no better preparations of antigens were available, and the presence of infection with pseudotubercle bacilli might also stand in relation to our failures in obtaining satisfactory results, further tests were abandoned and no additional serological studies were undertaken.

An attempt was made to demonstrate lysis *in vivo* by the reproduction of the Pfeiffer phenomenon. Two guinea-pigs, Nos. 43 and 53 of the group, that showed a complete complement-fixation, and one, No. 14 of the group that showed a partial complement-fixation, were selected for the experiment. Each animal with a separate control was infected with 200 times the supposed lethal dose of the culture employed in all these experiments. Exudate was taken from the peritoneal cavity of each pig and of its control, at intervals of two, four, six and twenty-four hours after the infections were made. The slides of this experiment were studied and examined by Capt. S. R. Douglas who reported that he could find no appreciable difference between the exudates of the immunized animals and those of their controls. These animals all died later; tubercle bacilli were found in all lesions; no cultures for bacilli of pseudotuberculosis were made.

Before infecting the treated animals, eight were killed which had shown negative results in the complement-fixation test, in order to ascertain the probable prevalence of pseudo-tuberculosis. Five of the eight showed lesions which were undoubtedly of pseudotuberculous origin and the related organisms were obtained in pure cultures from two of them. This gave little prospect for a sufficient number of unobjectionable experiments, inasmuch as we considered it but just to comply with Dr. von Ruck's condition that normal animals were necessary in order to resist infection, and that failures in animals which are diseased or have pseudo-tuberculosis, must be eliminated from consideration.

The remaining forty-three animals were nevertheless all infected, together with controls, as will appear in the following tabulation, because we hoped that something of value might be shown on their autopsies, to compensate us for the time and labor expended upon their treatment.

In our tabulation it will be observed that we record our findings only in regard to the presence or absence of tubercle bacilli, to the exclusion of the examination of sections. In this respect we are fully conscious that the simple presence of acid-fast rods is, in itself, not an absolute proof of tuberculosis, and that it is essential to demonstrate typical histological tubercles, in order to establish such a diagnosis. For this purpose, specimens of all doubtful lesions were preserved at the time when the autopsies were made, but, in view of the great prevalence of pseudotuberculosis, as found during the course of the experiments, and because of the fact that it would be necessary to exclude such animals from consideration, it was doubtful whether the large amount of labor required for preparing and examining sections was justified at all. The question, which had been previously discussed with Sir Almroth Wright, was decided by limiting the examination to the search for tubercle bacilli in smears made from caseous or macerated tissues, in both principals and controls.

Our results in these experiments are given in three groups, corresponding with the degree of complement-fixation observed in testing the respective sera.

It will be noted that our infections failed entirely in several of our controls for the treated animals, which obscures the results in the principals. The

culture from which the emulsion was prepared, was the same as the one used for the bactericidal experiments, in which the infections with 0.01 mgr. appeared to have been very near to the minimal fatal dose. Less than one week intervened, however, between these infections, and the only factor

that we can consider as most likely to account for the lack of virulence in some of the controls is, that there was a difference in the number of living tubercle bacilli contained in the respective emulsions. These were made in the same manner for both series of infections, a sterile physiological salt solution being used in their preparation, and the emulsion was examined microscopically to assure uniformity of distribution of the tubercle bacilli. The bacilli were, however, weighed on different chemical balances. Those for the emulsion used in the bactericidal experiments were weighed on the balance of the Inoculation Department, which appeared to lack in accuracy. Consequently the more sensitive balance in another department was resorted to for weighing the tubercle bacilli for preparing the next emulsion. Further, while the dose of 0.1 c.c. of the emulsion, equalling 0.01 mgr. of tubercle bacilli, for the bactericidal experiment, was apportioned to the several tubes for incubation on the same day on which the emulsion was made, that employed for the infections under consideration was made on the preceding day and stood for twenty-four hours before it was used. It is therefore possible that the number of tubercle bacilli was less, because of more accurate weighing, or that the normal salt solution favored the clumping and spontaneous agglutination of the tubercle bacilli; or then both conditions may have obtained and influenced the results. The emulsion was, however, well shaken each time before the syringe was filled.

Under the circumstances we submit these experimental results in guinea-pigs treated with vaccine without other comment than that, as a whole and irrespectively of dosage or mode of infection and of the influence of pseudotuberculosis, they seem to show a difference in favor of the treated animals, which does not, however, appear decided enough to warrant positive conclusion.* On the other hand, our results in the bactericidal experiments were clear in their import, and they appear to confirm Dr. von Ruck's claims that active sera, taken after one or more doses of vaccine, reduced the virulence of tubercle bacilli *in vitro* sufficiently to prevent infection in guinea-pigs, whereas in like experiments with sera taken before vaccination, and in the virulence-controls of both series the animals acquired tuberculosis.

We owe many thanks to Sir Almroth E. Wright, who so kindly permitted the attempt to ascertain the facts in regard to this work. His earnest cooperation and desire to see at first hand the evidence on which these claims are based was a source of great satisfaction. It had been hoped that he might add some personal comment on the results and conclusions of this work. His journey with the Expeditionary Force in France, from which he has not yet returned, seemingly makes this impossible. We also tender our thanks to Dr. Parry Morgan who assisted during the earlier work, and to Capt. S. R. Douglas whose continued interest and counsel were of great value to us.

*It is but fair to state that, on the conclusion of the autopsies, a cable was sent to Dr. von Ruck, stating that the experiments had been successful in about 43 per cent. of the treated animals, a conclusion which had been arrived at by comparison with the controls, with reference to the presence of absence of tubercle bacilli in the lesions found on autopsy. It is on this account that we believe the result to be in favor of the vaccine and that, in order to obtain unobjectionable results, the experiments should be repeated upon normal animals, with infections in which the virulence of the cultures is even and uniform.

THE DIAGNOSIS AND TREATMENT OF POLIOMYELITIS.*

BY WALTER L. BARBER, M.D.,

WATERBURY, CONN.

A FEW years ago if I had been asked to prepare a paper on this subject, it would have consisted of the following sentence: The diagnosis of poliomyelitis is not recognized until paralysis appears and, when known, no treatment is of benefit. To-day, after close study and experimental research, much has been discovered and can be written on the subject. The term poliomyelitis is in use because, on examination after death, it gives the method of classification, based on the lesion found. It is still popularly known as infantile paralysis, probably because it is more frequently seen in infants and young children, although it does occur in adults.

As a preliminary to my paper, and that it may serve the purpose of bringing before you the symptoms of the disease, I will give briefly the history of a case.

D. C., the little seven-year-old daughter of one of our wealthy men, was taken ill three days after her return from her summer home at the shore. Previous to her seizure, she had been in the best of health. From the best information I could obtain, there had been no poliomyelitic infection prevailing either there or in our city. The onset came suddenly while she was at school. It began with a chill, severe headache, a temperature of 102° or more, nausea and vomiting, muscular tenderness, dilated pupils, and a little mental confusion. The symptoms were much like those of intestinal toxemia or acute indigestion. By the fifth day I began to fear typhoid fever and took the blood for a Widal test. She was then suffering severe pain in her left arm and leg. The reflexes were normal at that time but I noticed a strabismus of the muscles of the left eye and, when I asked her to draw up the lower limbs, only the right one could perform the function. On the sixth day, the diagnosis was evident from the partial paralysis of the muscles of the left shoulder group and complete paralysis of the gluteals, quadriceps, and peroneals of the lower extremity of the right side. The child could not sit up in bed or move the leg. The faradic irritability was lost, as were the reflexes of the patellar tendon. There was no impairment of sensation or incontinence of urine. Marked atrophy of the muscles did not occur. Improvement soon began and continued. As time went on the muscles of the arm regained their normal function. Her general health was excellent and she began to play and to use the muscles. Three months after the onset, a slight spinal curvature was noticed and a limp, when walking, was evident, showing cessation in the growth of the bone. Soon after, at Christmas time, she developed pneumonia and was very ill for six weeks, during which time all treatment was suspended. As she began to get about again, the improvement in her muscle tone was very marked, all due, I believe, to the enforced quiet and rest that was absolutely necessary for her while undergoing recovery from the lung affection.

In these days, the increasing prevalence of poliomyelitis makes it one of the most important and practical diseases for our investigation and discussion. Each year, since 1907, has seen its epidemic

*Read at the meeting of the New Haven County Medical Society, Oct. 2, 1915.

somewhere which has left behind it hundreds of victims. Massachusetts had 234 cases that year. In 1908 the disease raged in New York City, and more than two thousand children were attacked. In 1914 it prevailed in epidemic form extensively in Vermont. I am convinced that sporadic cases often occur with symptoms so mild and transient as not to be recognized.

How helpful to the medical profession, then, by way of the nasopharynx and along the lym- continued work of Flexner and his co-laborers. In their laboratory, through experiments with monkeys, they have discovered:

1. The disease is due to a germ, one of the filterable organisms, so minute that it can pass with readiness, and with no loss of energy, through the pores of a porcelain filter—the smallest one ever discovered by the microscope.

2. By the action of this germ the disease becomes infectious and may, or may not, produce cases, sporadic or epidemic in form, severe or mild in type, depending on its activity and virulence.

3. The entrance of the virus into the system is by way of the nasopharynx and along the lymphatics which follow the filaments of the olfactory nerve to the cerebrospinal fluid.

4. The same portal of entry can, and probably does, act as the pathway of exit for the germ, to be transmitted by contact or carrier to new fields for reinfection.

5. An early diagnosis of the disease, by the finding of organisms in the spinal fluid, is possible but not very probable.

6. One attack tends to afford protection from the disease in the monkey, but up to the present time, with any mixture of virus or serum, immunity in the individual has not been accomplished.

Having stated these important and decisive facts, we can briefly elucidate on the development of poliomyelitis and its attendant results. When the germ reaches the spinal cord by way of the spinal fluid it at once begins active work on the lymph and blood cells of the gray matter of both the anterior and posterior horns, but chiefly the anterior. The arterial supply is greater and richer at the lumbar and cervical enlargements of the cord; which accounts for the lesions found in these zones. When the former is involved the muscular group of the lower extremity is impaired, and when the inflammatory process impedes or destroys the cells of the cervical ganglia the muscles of the upper extremity are paralyzed. The irregularity in the branching of these vessels of supply determines the question as to left or right side paralysis. Of course, at the onset, no one can foretell the result of the infection. It may, or may not, affect the nerve cells. It will all depend on the virulence of the organism and the resistance of the patient. No doubt, many cases are mild and abortive because of the small area congested, the cell function being only incapacitated. Paralysis generally follows the stage of invasion within three or four days. The loss of motion may be rapid or slow. With a severe attack, a large number of voluntary muscles of one or both extremities are simultaneously affected. When the paralysis is gradual, the muscle impairment extends from one group to another, covering several days. The leg muscles are often affected. Cases of partial paralysis occur about twice as frequently as those of complete paralysis. Loss of function in the muscles of the spine is rare, and greatly to be deplored because of its relationship to spinal curvature. Muscles that have not improved in three or four months will never entirely recover. Marked atrophy then exists. The muscle is changed into fat deposit and slowly disappears. This is due to the degeneration of the cells in the anterior horn of the gray matter of the cord, thus interfering with the proper nutrition and function of the nerve and muscle.

Having devoted a few minutes to the end results of this insidious and much-dreaded disease, we will take up one of the divisions of our theme—its *diagnosis*. Generally, the attack is so sudden—like a flash out of a clear sky—that poliomyelitis is not recognized until the paralysis makes plain the localizing of the infection in the spinal canal. Often, in the morning, after only a restless night, the useless member is discovered. If the onset is of three or four days' duration and the cerebral symptoms are unimportant, intestinal toxemia or the beginning of typhoid fever may be suspected. Many abortive cases or those unattended with cell destruction are never diagnosed. Of course, the disease can be, and often is, confounded with cerebrospinal meningitis. Until more knowledge has come to us, I can not see how, clinically, such a diagnostic mistake can be avoided. The two diseases attack children alike; are caused by organisms that reach the nerve centers through a common portal of entry, the nasopharynx; and in both the infectious virus is eliminated from the same site. Epidemic cerebrospinal meningitis occurs generally in the winter months, while epidemic poliomyelitis is said to prevail more often in summer; but neither one will prevail unless the germ is at hand to convey it. In both cases the spinal fluid should be withdrawn and examined. The Kernig symptom—that is, an inability to extend the leg on the thigh when the latter is flexed on the trunk—is obtained in all cases of cerebrospinal meningitis at some period of the disease; so, also, are marked rigidity, petechiæ, and opisthotonos, which symptoms, as a rule, are never found in poliomyelitis, except possibly in some of the bulbar forms. As a matter of fact, the diagnosis probably will not be made until the malady is self-evident.

The *treatment* of poliomyelitis, as in all diseases due to germ infection, may be divided into two varieties: first, the specific treatment directed to the specific cause; second, the symptomatic, directed to the morbid changes and their manifestation as brought out by the symptoms. We now know positively—what had been for a long time suspected—that the cause of the disease is an invasion into the spinal canal of a horde of virulent organisms so intrenched that we are unable to destroy them or lessen materially the damage they may inflict. In our desire to assist the patient, increase his power of resistance, and diminish the action of the infection, we must not forget those in health beside the patient, who are quite liable to contract the infection. Every effort must be made toward prevention. Isolate the patient and his surroundings; notify the quarantine authorities; make the nurse and family understand the absolute necessity of destroying or sterilizing all articles that have come in contact with the virus, which we now know emanates from the nose and throat; keep the parts well sprayed with solution of hydrogen peroxide; adopt rigid precautions against the spread of the disease such as have been essential in other infectious diseases, and administer hexamethylenamine to the unaffected members of the family. We believe, today, that not only the patients are contagion car-

riers, but the well ones who have come in contact with the disease. It adds to the difficulty of prophylactic measures, but it seems desirable to keep the patient in quarantine for at least five weeks. No organisms have been found, as yet, in the fecal or urinary excretions, but I am convinced it is wiser and much safer to disinfect them carefully throughout the disease, at any rate at the onset, as we are accustomed to do in typhoid fever.

There is no known specific or remedy for poliomyelitis. Flexner and his associates, to whom the writer is greatly indebted for some of the essentials of this paper, have not, up to the present time, succeeded in producing therapeutic serum that will neutralize or destroy the effect of the virus, when once the system becomes infected. Dr. Flexner says: "Finally, the serum treatment of poliomyelitis must, at the present time, be regarded as strictly in the experimental stage, and it cannot be predicted how soon, or whether ever at all, such a form of specific treatment of the disease will be applicable to the spontaneous epidemic diseases in human beings." Personally, I have faith to believe that, having discovered the nature and type of the virus and so many important points in regard to the phenomona of immunity, it will not be long before a serum will be secured which will possess sufficient therapeutic value to mitigate the end results of the disease or, at least, to prove of some help in its prevention.

After accomplishing all that is possible in the way of prevention, and having no measure of specific treatment of value to offer, we must rely entirely on the symptomatic medication. Naturally, the bowels should be thoroughly evacuated—my favorite drug being calomel, not alone for its bile-stimulating effects, but also for its germicidal and antiseptic qualities. An icebag should be applied along the spine. The occurrence of convulsions would call for the use of chloroform carefully administered. The headache, tenderness of muscles, and extreme restlessness require acetphenetidin in sufficient doses to relieve and make comfortable the patient. For these symptoms, however, in place of drugs, I prefer to use heat in some form—the electric heating pad always when the house is wired for the current. I know of nothing so valuable in that form of muscle pain. Just how much good heat does in thwarting the progress of atrophy that is present in the later stage of the disease is a question, but it is a helpful method of supplying warmth to the affected parts which are generally from one to two degrees of temperature lower than the unaffected member. For a few days it is always best to administer large doses of hexamethylenamine, combined with benzoic acid for its germicidal action. The use of this medicine is also based on the fact that it is found in the cerebrospinal fluid, and has already given some evidence of a favorable action on inflammatory processes in the brain and spinal canal. Flexner's experiments with this drug showed that it had some immunizing effect, but was of no value after the infection had occurred. Children are not monkeys, however, and drugs may operate on them differently. For example, Dr. Lovett says: "In July, 1911, three children in one family were affected at intervals of three or four days with fever, prostration, and gastrointestinal disturbance. The diagnosis of the first case was made only after the second child was in the height of her attack and before the third was affected. The first child received no hexamethylenamine, the second had a little, and the third had large doses from the beginning. The first child was severely paralyzed from the waist down, the second had weakness of the legs and back for a few months, and the third had no muscular involvement. All were equally sick." After such an observation, its use early in suspected cases seems highly desirable.

Another drug that I want to mention is strychnine, to be given only after all inflammatory effects have subsided. It acts directly by stimulating the motor ganglin, thus counteracting the increasing tendency to muscular atrophy. The consensus of opinion is that its use favors nutrition of the paralyzed parts by its effects on the sympathetic nerve. It should be given at first in small doses, increased week by week, and continued over a long period. It is just as beneficial when given internally as by the subcutaneous method.

As regards the use of electricity in poliomyelitis, authorities disagree, and quite emphatically too. Last winter I asked Dr. William B. Pritchard of New York to see a case with me (the one I have reported), and he suggested the use of galvanism in doses of five milliamperes for ten minutes every day. This was continued for several months, or until the muscles began to respond to the interrupted current; then both were used for months. As a matter of fact, the child still continues to have electricity, though away at the shore and under the care of Dr. Wallace. Whether the treatment was helpful, or in the least beneficial in improving the muscular tone, or whether the condition—which has been slow enough—follows the stimulation of strychnine and the added nutrition to the impaired muscles from good food, fresh air, and delightful circumstances, I am unable to state. There are, however, real doubters of its efficacy. Dr. Lovett of Boston has this to say in regard to it: "Electricity is less highly regarded in the treatment than was formerly the case. The unintelligent use of it, month after month, to the exclusion of other measures, has been one of the handicaps which has stood in the way of the best progress in many cases. It is quite possible that it may improve the muscular condition. Statements of its value rest, as a rule, on bare personal assertion or on the unusually rapid improvement of the individual cases; but cases vary greatly in their rate of improvement, and the only way to judge of the value of electricity is to use it on one side of the body in bilateral cases, and use the other side as a control. In the winter of 1913-1914 some cases in private practice were given daily treatments of galvanic electricity on one side and none on the other, while daily muscle-training was being given by my assistant, who was not told which side was receiving the electrical treatment. At the end of some months she was asked if either side had showed more rapid improvement than the other, and no difference had been noticed. This simply confirmed my general experience of many years of less careful observation." I, myself, feel that the use of electricity is too often left to the nurse or some other inexperienced person. Applications, when used too long or misdirected, fatigue the muscle and do harm.

Massage should go hand in hand with the electricity. It induces a better blood supply; hastens the lymph along the channels; promotes a warmth of the parts, thus preventing muscular deterioration. I have little knowledge of muscle-training or the manner in which it is taught, but I do know that such orthopedists as Lovett of Boston and Wallace

of New York speak of this method with increasing favor, especially in partial paralysis. Dr. Ruhräh, in "Progressive Medicine," reviews the method, and I quote: "The last part of the treatment consists in muscle education. This is best done before a mirror—the patient trying to move the muscle, and when this cannot be done voluntarily, having the person superintending the treatment make the necessary motion. This is difficult in young children, but can be tried in all children over three years of age. This should only be continued for a short time at one sitting. In the correction of deformities one should be particularly careful to avoid exercising the healthy muscles by improperly used exercises. The healthy muscles may be developed very much more rapidly than the deformed ones, thus developing a worse deformity than when the treatment was started. It is therefore necessary to explain to the one directing the treatment just what should be done, and he should not deviate from the directions given. . ." One voluntary contraction of a muscle is now thought to be of greater value than any produced by electricity.

In conclusion, I want to add that, for the deformities that must and will occur in all severe cases, tendon transplantations and bone repair have, by our steady advance in knowledge, reached a stage of perfection never before equaled; to an expert orthopedist I commend early your case, if improvement ceases.

*Child still employing slight support and using electricity, July 16, 1916.

TREATMENT OF UNSTABLE SEMILUNAR CARTILAGES OF THE KNEE JOINT.*

By ROYAL WHITMAN, M.D.,
NEW YORK.

THE disability first classified as internal derangement of the knee joint is now recognized, as caused in the great majority of cases, by displacement of the internal semilunar cartilage.

The injury is comparatively common, but I am inclined to think that its characteristics are more familiar to those interested in athletics than to physicians, many of whom have but the vaguest ideas as to its causes and consequences. I shall, therefore, describe briefly its anatomy as a basis for argument in favor of effective treatment.

The semilunar cartilages are similar in structure and function to the glenoid and cotyloid ligaments that enlarge and deepen the articulating surfaces about which they are attached. They differ, however, in that they are separated into two parts, and being loosely bound to the margin of the tibia move upon its surface through a range of about one centimeter. In adaptation to the movements of the joint, they change also in contour, becoming longer and thinner in full extension, and correspondingly shorter and thicker in flexion.

The internal cartilage, following the border of the tibia, is more properly semilunar in outline as compared to the external. It is more closely connected with the lateral and capsular ligaments, and is subjected to greater strain by the lateral mobility of the joint. At 30 degrees of flexion, for example, the tiba may be rotated outward on the femur through a range of 30 degrees, or until it is checked, chiefly by tension on the internal lateral ligament. Internal rotation, on the other hand, is limited to 5 or 10 degrees by the resistance of the crucial ligaments.

*Read before the Orthopedic Section of the New York Academy of Medicine, April 21, 1916.

Displacement of the internal cartilage is usually caused by external rotation of the tibia on the femur, or by internal rotation of the femur upon the fixed tibia while the knee is flexed. The sudden strain upon the internal lateral ligament, whose deeper layer is attached to the cartilage, tears the latter loose from the margin of the tibia and displaces its anterolateral portion backward toward the interior of the joint, so that it is caught between the bones when the limb is extended. The general impression seems to be that the displacement is in the other direction, and that the cartilage projects beyond the margin of the tibia, where it may be detected on palpation. This, however, must be very unusual.

In typical cases the injury occurs during violent exercise, as in athletic contests. Thus in England it is known as the "footballer's knee." There is a sensation of sudden strain, and often of something slipping within the joint, usually severe pain and immediate disability, the characteristic symptom being inability to extend the limb completely. Replacement may be spontaneous, but manipulation is usually necessary. An effective method is to place the patient on the back, and to flex the knee on the thigh and the thigh on the trunk. One then abducts the tibia on the femur to separate their inner margins, then rotates the tibia outward and inward and extends the limb. During the manipulation the patient usually feels something slip, and free motion is regained. Effusion often follows the accident, and sensitiveness about the inner side of the joint persists for several weeks.

The immediate treatment after reduction should be fixation for a time sufficient for the repair of the strained or ruptured ligament and reattachment of the cartilage to the tibial margin. Apparently for want of treatment, or in spite of it, such security is not often established, since recurrence is the rule under predisposing conditions. If it occurs at infrequent intervals the reaction is usually severe. If it occurs often the joint becomes more tolerant, the patient learns some effective method of readjustment, or there may be no so-called locking of the joint, the disability being rather from a sense of insecurity than from the direct consequences of the displacement. This insecurity limits activity, not only in athletic contests but under ordinary conditions as well. The patient instinctively avoids predisposing attitudes and movements, and usually knee caps, bandages, and even apparatus are worn to assure security.

The injury is most common in young men, but it is by no means rare in young women, and although the immediate cause is injury, weak feet, weak muscles, and bad attitudes must be recognized more often as predisposing factors in this sex.

Occasionally, the consequences are more serious, when, for example, the cartilage remains displaced, so that limited motion, pain, and synovitis persist indefinitely. In these cases partial recovery is explained by disintegration of the obstruction or accommodation to its presence. In other instances, the cartilage may be broken, or crushed by direct violence without actual displacement, and there are others in which injury or displacement is a complication of degenerative changes in the joint.

This paper is chiefly concerned with the ordinary cases in which the symptoms are recurrent, and are directly dependent on the displacement. In this class, although complete restoration of the function of the cartilage may be possible, it is probably uncommon, the so-called cure being in most in-

stances simply an accommodation to the weakness.

A sense of insecurity is in itself a serious handicap, while recurrent displacement endangers the function of the joint. Repeated injury to the synovial membrane which covers the cartilage leads to hypertrophy; effusion to weakness; distention to laxity of the ligaments; and the secondary muscular atrophy which is almost always present increases the functional disability. In cases of the more serious type, changes characteristic of chronic arthritis follow, which may serve as a predisposing cause of tuberculous disease.

In cases, therefore, of persistent instability, in which the inconvenience is at all serious, particularly if a bandage or other support must be worn constantly, removal of the cartilage is indicated.

The operation would be advisable even if the cartilage were essential to normal function, since if it is loose it is practically a foreign body. It is not, however, thus essential. Experimentally, its removal does not affect the movements of the joint, nor is function impaired in those cases that have been operated on.

It is true that stability may be assured in most instances by a brace that prevents lateral mobility, but the treatment is somewhat burdensome, the outcome uncertain, and, if successful, the result no better than that which is practically assured by the removal of the unstable cartilage.

What may be classed as relatively early operative treatment is, I find, not usually advised or approved either by physicians or surgeons. The operation is thought to be dangerous, requiring prolonged convalescence, and resulting in a weakened or possibly stiffened joint. From practical experience, however, it may be stated that the immediate discomfort and the succeeding disability are usually no greater, and often are less, than when caused by the occasional displacement. In fact, functional recovery is far more often delayed by relaxed ligaments, atrophied muscles, and hypertrophied synovial membrane—the results of persistent irritation and injury—than by the operative removal of the cause.

The only reasonable argument for delay when the diagnosis is clear and the disability recurrent is the danger of infection, and this may be reduced to the most remote possibility by the simplicity and directness of the operative procedure. In favorable cases the cartilage may be removed in a few minutes. There is no necessity for exploration of the joint, and the only assistance required is for retraction of the tissues.

Particular attention is, of course, paid to cleanliness. If time permits the part may be shaved, washed, and protected by gauze for several days before the operation, when it is prepared with iodine in the usual manner. An Esmarch bandage is usually applied in order to avoid swabbing and the like. The patient is then drawn down to the edge of the table, so that the leg, flexed to a right angle at the knee, hangs dependent, as suggested by Jones. In this attitude an incision, slightly convex forward, is made midway between the border of the patella and the condyle, its base being just in front of the internal lateral ligament. The joint is then opened. In most instances the displacement of the cartilage is evident, since the tension on the capsule of the dependent leg draws it upward and away from the tabia. Not infrequently it is detached anteriorly and displaced backward. It may be fractured, or thickened and pedunculated, but in the ordinary case it is not greatly changed in shape. It may be normal in appearance or yellowish in color if the disability is of long standing. By extending the incision downward the cartilage may be divided into two parts; the anterior or free half is then easily detached by a slight pull with the forceps. The posterior part is attached to the capsule, and often to the tibia, and must be separated with the scissors. It is the rule, apparently, to cut away only the loose anterior portion, but I have always removed the entire cartilage, and thus a possible cause of further trouble. In most instances, the evidences of previous irritation and injury may be seen in congestion of the tissues, and particularly in the hypertrophy of the synovial membrane.

After removal of the cartilage the synovial membrane is closed with fine catgut, and the capsule and other tissues in layers with stronger sutures. No drainage is used. The knee is firmly bound with a gauze roller, and a light plaster splint holding the limb in slight flexion is applied. Apparently the bleeding after suturing is insignificant, since no inconvenience has been noted from this source. The plaster splint is of service in lessening the discomfort caused by sudden movements during the sensitive stage. The patient usually remains in the hospital for a week, though not necessarily in bed, activity being regulated by the sensations.

The plaster splint is retained for about two weeks, in order to permit of repair of the capsule. The knee is then strapped to replace the support, and to guard against strain.

The patient is instructed to cultivate an elastic gait in walking. If, as is often the case, there is a tendency toward valgus, the soles are thickened on the inner border, or arch supports are applied if the deformity is more marked, and appropriate exercises are prescribed.

In cases of a favorable type cure is practically complete in a few weeks. In those of long standing, in which the muscles are atrophied, the ligaments relaxed, and the internal structure of the joint disorganized, recovery is slower, and a supporting apparatus may be indicated, but the improvement is immediately apparent and progressive and the result is satisfactory to the patient.

The characteristics of the varieties of the injury and disability may be illustrated by selected cases.

Case I.—The unreduced type. A vigorous young man, 25 years of age, an acrobat by profession, was seen in May, 1914. Three months before, while seated in a chair with the left leg flexed beneath the seat, on turning suddenly he felt something snap in the knee. The pain was acute, and he was unable to extend the limb. The next day a physician attempted to reduce the deformity, but the pain caused the patient to faint. He used crutches for a month, and had since limped about with the aid of a cane. There was marked atrophy of the thigh, slight limitation of extension at the knee, slight outward rotation of the tibia, and the characteristic sensitiveness to pressure on the inner side of the knee. Operation was advised, but the patient was not seen again.

Case II.—Illustrating secondary, or arthritic changes following displacement. A woman 50 years of age was seen in April, 1914. Apparently the knee had been normal until injured by a misstep about 18 months before. The accident was followed by pain, swelling, and inability to extend the limb. Apparently, although the history was indefinite, flexion had since persisted. Nine months after the accident an attempt had been made to reduce the displacement, but without success. The patient had since suffered much discomfort in the knee, and the gait was very awkward because of the flxion to 140°. The joint was infiltrated and sensitive to movement and pressure. Degenerative changes in the joint were ap-

parent in the *x*-ray picture. On operation, the internal cartilage was found to be displaced, and of a yellow color. The synovial membrane was thickened. The articular cartilage of the femur was hypertrophied at the margins, suggesting arthritis deformans. Flexion contraction was so resistant that complete extension was not attempted. In this case it was by no means certain that the arthritis was dependent on the injury, and the prognosis was very guarded, but under rest, massage and protection, practically complete recovery followed.

Case III.—Severe and disabling symptoms persisting in spite of protective treatment. A colleague, 43 years of age, displaced the internal cartilage in April, 1911. This was treated by the most approved conservative methods—by a plaster support, by a protective brace, by strapping, massage, and the like for 6 months. He was meanwhile never free from discomfort, and was frequently disabled by recurrent displacements when support was removed. Eventually he became seriously alarmed because of the possibility of tuberculous disease, and consented to operation. In this case the cartilage was displaced and broken into two parts. Complete and permanent functional recovery followed.

Case IV.—Illustrating persistence of disability for many years. A man 39 years of age was seen in March, 1914, the disability dating from his school days. The knee was weak, and he was constantly solicitous of it. It gave way, and the displacements, which he reduced himself, were becoming more frequent, and were frequently accompanied by synovitis. He had worn various appliances without permanent benefit. The cartilage was removed June 16, the interior of the joint showing the usual congestion. In three weeks the condition of the knee was what the patient considered normal before the operation. Recovery was practically complete in 6 months.

Case V.—A case of the favorable type. An athletic girl of 19 was seen in October, 1913. About a year before, the cartilage had been displaced while she was playing basketball. In August, displacement again occurred, and also on three occasions since then, the pain being so extreme that the patient's health has been impaired by it. The cartilage was removed in November, 1913. In three weeks she was practically well.

Case VI.—Removal of both cartilages. An athletic girl of 20 was seen on April 6, 1911. She had injured the left knee at basketball five months before. There had been some pain and stiffness at that time, but no limitation of motion or swelling. Conservative treatment relieved the symptoms, but 6 months later high kicking induced a severe attack. Since then the discomfort had been constant, and the patient was often conscious of something moving in the joint. The operation was performed on February 1, 1912. To my surprise there was almost complete detachment of the external as well as of the internal cartilage, and both were removed. Recovery was rapid, and practically complete.

Case VII.—Illustrating occupational disability. A man of 32 was seen on December 12, 1912. He was an expert marksman, but the danger of displacement prevented the necessary kneeling position. Removal of the cartilage gave complete relief.

Case VIII.—Occupational disability. A young football player who often displaced the cartilage when kicking the ball. In this case the cartilage was very much hypertrophied, and could be palpated by the patient himself. Removal relieved the symptoms.

Case IX.—Occupational disability. A school boy sixteen years of age had been unable to engage in athletics because of recurrent displacement during a period of two years, and on this account desired relief. He was practically well three weeks after the operation.

Case X.—Illustrating the distinction in symptoms between displacements of the internal and external cartilages. A boy of sixteen was seen in August, 1914. For three years a peculiar snapping sensation had been noted whenever the knee was flexed. There was no locking, swelling, or local sensitiveness—only, as he described it—a deadened feeling in the limb. On operation the external cartilage was found to be detached and displaced backward, obstructing movement, and causing a peculiar jar and displacement of the tibia when it was overcome. Recovery was complete and permanent in three weeks. Several similar cases have been seen in which a "snapping knee" was the most noticeable symptom.

In my experience there is no operation more uniformly successful than this, or in the confirmed cases more directly indicated, since a loose cartilage is of no functional value, but is a dangerous encumbrance to which the habits of the individual and the structure of the joint must accommodate themselves to their mutual disadvantage.

283 Lexington Avenue.

THE NATURE OF THE LEUKEMIAS; THE PATHOGENESIS OF ACUTE LYMPHATIC LEUKEMIA.

By RICHARD STEIN, M.D.,

NEW YORK.

VISITING PHYSICIAN TO THE GERMAN AND LEBANON HOSPITALS.

In this study I will attempt to bring the subject of the nature of the leukemias to a clearer clinical understanding by discussing some phases of this large subject, partly as the result of personal experience, partly as the fruit of the study of the large amount of material which has been gathered together since Virchow's first description.

Virchow spoke of the affection as leukemia, the disease with white blood, naming it from its most charactertistic symptom. He noticed that in one group of cases the most predominant clinical symptom is a marked splenic engorgement, while in another group multiple glandular swellings dominate. Thus Virchow was led to differentiate a splenic form of leukemia presenting a saturation of the blood with white corpuscles containing polynuclear cells from a lymphatic form of leukemia in which the blood contains the lymphatic cells in large excess. In consequence, Virchow speaks of a splenemia and a lymphemia. Even at that date Virchow recognized the universal implication of the lymphatic tissue in the lymphatic type of the disease, as well as the concomitant anemia, the oligocythemia.

Neumann's discovery of the hematopoietic function of the bone marrow and of the changes found in the marrow in leukemic disease were of a nature to modify the views originally held of the histogenesis of the leukemias as referred to above; the splenic form of the disease was now shown to be characterized by a myeloid metaplasia of the spleen as well as of the bone marrow. Thus lymphemia and myelemia were now recognized as characteristic of distinct types of leukemia. Thus it already becomes apparent at this point that in the leukemias we do not see diseases of distinct organs, but of special types of tissues, the lymphatic and the myeloid. To study the pathology of the leukemias satisfactorily, it becomes necessary to investigate the changes in all the tissues, but especially those of the hematopoietic organs. In them we shall find the myeloid or the lymphatic metaplasia, according to the character of the leukemia. The proliferations are of a uniform character and easy of interpretation. Of late a number of chemical tissue reactions have been devised which serve to differentiate the lymphoid and the myelogenous tissues.[1]

The blood has been looked upon by some as a tissue in which the various corpuscular elements can be compared to the cellular structures, and the serum looked upon as the intercellular structure, just as if the blood were a stable woven tissue, not simply an aggregation of cells suspended in a menstruum. Following up this idea, the blood is imbued with certain formative qualities of a developmental as well as of a regressive quality. Led on by this theory, as well as by the hope of incidental pathogenic findings, many investigators of the diseases of the blood have tried to find the solution of the

mystery of leukemia in some special formation in the blood itself. Invariably these investigators have been misled by the will o' the wisp of the fascinating polychrome blood morphology.

By many investigators leukemia was early looked upon as a tumor formation, and the term metastasis, which is still current in speaking of leukemic proliferation, has been persistently used up to our own time. Among modern authors, Banti, Ribbert and Benda are inclined to the tumor theory on account of the seemingly aggressive character of the leukemic proliferation into the surrounding healthy tissues. This apparent malignancy, however, on close study proves to be nothing but a metaplastic overgrowth. Since we are still in ignorance of the essential nature of malignant growth, a further discussion of the theme, is leukemia a malignant growth or not? seems fruitless. At the same time it is advisable to discard the term metastasis in this connection, as this term is associated exclusively with the idea of malignant tumor growth; this, however, is extraneous to the conception of leukemic disease generally held at the present day.

This question of the tumor nature of leukemia has more than a theoretical interest for the reason that there is a class of cases which resemble the leukemias in their clinical aspect, but which, as soon as a blood examination is made, at once appear as diseases of a totally different nature. The blood in these cases is not leukemic and shows no special characteristics more marked than those encountered in clinical conditions of various kinds. Since Cohnheim cases in this group have been called the pseudoleukemias. Lately cases of this kind have been described which have stood for the first stage of true leukemias. Then there are forms of pseudoleukemias which are of a tuberculous, granulomatous or sarcomatous nature. Then there are cases described from time to time which it is necessary to group with the pseudoleukemias, their etiology being as yet undetermined, and because they are surely distinct from the leukemias proper. By a careful study of these cases we arrive at a certain delimitation of the leukemias toward allied clinical states, and incidentally widen our knowledge of the pathogenesis of the leukemias.

Ehrlich's color analytical studies of the blood, undertaken with a novel technique of fixation and stain, have contributed a form of research which can be employed to investigate with finesse the morphological characteristics of the cellular elements of the blood. This method, as applied to the study of leukemia, has given brilliant results.

It has been stated, in connection with this very subject, that morphological hematology has been very much overdone.[2] Morphological hematology has been used in a one-sided, routine fashion; the attempt is made to solve the pathological or biological problems by the exclusive use of Ehrlich's methods of color study of the blood constituents. No doubt a great deal has been learned by this method in leukemia and other so-called blood diseases. But at the same time mention should be made of the fact that some of the broad conclusions which were drawn by Ehrlich himself in his original studies of the granulations had to be considerably modified. And as to the solution of some of the problems of the origin, development, and course of the conditions under discussion—just as in other investigations—these can only be reached by improved histological, bacteriological, and experimental studies, which, until recently, have not held pace with morphological blood studies. Thus, for instance, the theory of the evolution of the leucocyte, based, as it largely is upon the study of morphological hematology alone, can be seriously questioned. And with all the infinite pains which have been expended upon the investigation of the histogenesis of this disease, the springing points from it are still unsettled, and little or nothing has been added to our conception of the pathogenesis and the etiology of the leukemias. This is also in part due to a preconceived notion still held by some of the foremost hematologists, that leukemia—in view of the phenomenal blood changes—are different from all other known diseases. We shall see that this is unfounded. By the empirical method of observation the clinicians have brought the subject near to a solution. Leukemia is based on well-known pathological and clinical processes.

What then is leukemia? In order to be as brief as possible, I have cut the question in two or rather in four, and will confine myself on this occasion to the question: What is acute lymphatic leukemia?

Ever since Ebstein's[3] publication of a case of acute lymphatic leukemia and of his monograph, it seemed more than probable that in acute lymphatic leukemia we are dealing with an infectious disease. Subsequently Albert Fraenkel's[4] series of cases could only tend to strengthen this view in the unbiased observer.

It is not the purpose of the writer to describe in detail all the clinical features of acute lymphatic leukemia with a view to demonstrate the infectious nature of the disease by analogy. For this purpose Ebstein's work may be studied with profit. The writer will attempt to prove the infectious nature of the disease by selecting one or the other striking phenomena commonly observed in well known forms of infectious disease which are similarly observed in acute lymphatic leukemia—first then, the phenomenon of leucocytosis, in this instance of lymphocytosis. Furthermore, he will point out certain clinical group characteristics observed in leukemic disease which are invariably found in the course of infectious diseases. Thirdly, he will describe certain cases which have all the cardinal signs of infectious disease and which are clinically, hematologically and pathologically analogous to, if not identical with, acute lymphatic leukemia. These cases range through various degrees of severity, from the comparatively mild type of infection to the severer and the fatal cases. Hitherto leukemia was invariably considered a fatal disease. By the study of this group of cases it is made evident that the light cases are nothing more or less than a phase of the severe and fatal cases of leukemia. And lastly by a short discussion of the status thymolymphaticus, which presents an important element in the pathogenesis of lymphatic leukemia.

Lymphocytosis.—According to Virchow, leukemia is a progressive leucocytosis. This definition holds good for all cases with rare exceptions. Now, aside from certain well-defined physiological states like hunger, digestion, pregnancy, lactation, and aside from certain variations of the leucocyte count due to stimulation or inhibition of the endocrine organs and the phenomenon of anaphylaxis, leucocytosis is exclusively and constantly associated with infection. The phenomenon of leucocytosis moves in definite cycles, varying in kind, number, and relative proportion according to the nature of the infection—according to certain principles of chemotaxis. Thus, thanks to the labors of Ehrlich and his fol-

lowers, we are now able to diagnosticate and prognosticate infectious disease, according to the nature of the accompanying leucocytosis. Thus in a well marked infectious condition we are led to expect a certain well-defined leucocyte count, which, in conjunction with other signs, will indicate the character, phase, or stage of that case of infection. If this count varies in the kind, number or proportion of the leucocytes, we at once look for complications to explain the atyphical or anomalous blood-count. This rule is as invariable as a mathematical law.

In the present state of our knowledge it is not easy to translate the formulas of the various leucocyte counts into the formulas of the biological blood reactions which give rise to the characteristic leucocytosis under varying conditions. Clinical experience has shown empirically, that some of the well-known infectious diseases instead of being accompanied by the usual polynuclear hyperleucocytosis, exhibit a marked degree of lymphocytosis. Among these may be mentioned variola, lues, tuberculosis, typhoid fever, malaria, pertussis, and some others. The infectious agent of each of the diseases named produces in all subjects who are successfully infected by them, not the ordinary polynucleosis, but a lymphocytosis, absolute or relative. There are certain infectious diseases on record in which the lymphocytosis induced by some special lymphotactic agent reached excessive figures. How can this be explained? Primarily by the character of the infective agent. All individuals react in the same way—in a general chemotactic sense—when infected with certain pathogenic bacteria. Bergel[5] has shown that the lymphocytes contain a fat-splitting lipolytic ferment. Applying this lipolytic property of the lymphocytes to the phenomena of infection, lymphocytosis may be defined as an antagonistic reaction of the blood (Abwehr reaction) against antigens of a lipoid character. Thus it is possible to induce local lymphotaxis by injecting fat into the peritoneal cavity. The lymphocytes take it up and split it up, by means of the lipase; the fat laden lymphocytes are transported into the spleen. In looking into the properties of the infectious agents of some of the diseases mentioned above in which lymphocytosis occurs, the bacillus of tuberculosis, the spirochete of lues, we find that both of these germs have a fatty covering; the lymphocytosis accompanying these diseases may be explained on this basis. It may be noted in this connection that as far back as our knowledge of leukemia extends it has been asserted that the disease develops on the basis of certain forms of cachexia due to severe infection of lues, malaria, or typhoid fever. We may infer that severe infections of a lymphotactic nature may prepare the foundation of a leukemic invasion—probably of a lymphatic nature—by unsettling the balance of the lymphatic and myelogenous tissue systems of the body. I will not dwell on the character of the cells encountered in acute lymphatic leukemia. It is not always the large lymphocyte as Ebstein and Fraenkel thought. In children and young individuals, the small so-called ripe lymphocyte may be the feature of the histological as well as of the blood picture.

The infectious nature of acute lymphatic leukemia must further gain support by drawing attention to the clinical grouping of the cases recorded hitherto, according to clinical type characteristics. There is first the enteric type described by Mosler, which is heralded by severe enteritis accompanied by bloody stools. This suggests a primary infection of the intestinal tract. Then there is the purpuric or Werlhof, or scorbutic type with hemorrhages from mouth and nose and hemorrhages into the skin purpuric enanthemata and exanthemata. Then a type frequently observed starts with an angina accompanied by glandular swelling of the neck. Again we have an aggravated form of the same type with ulceration and necrosis of the mucosa of the throat and nasopharynx, occasionally noma of the buccal membranes. In some of these cases the Klebs-Loeffler bacillus, in others the bacillus and spiral of Plaut-Vincent's disease were found. Although it must be conceded that catarrhal, ulcerative and necrotic changes in gums, fauces, and nasopharynx may partake of a secondary constitutional leukemic nature, the appearance of these lesions at the time or shortly after the inception of the disease with the accompanying infiltration of the lymphnodes of the neck and jaw make it more than probable that the tissues of the mouth, throat, and pharynx serve as the portal of entry of the leukemic infection, as they do in so many other cases of infectious disease.

Through the kindness of Dr. F. E. Sondern I am in the position to mention a noteworthy series of cases of Vincent's disease which have been studied by Dr. Sondern but not published as yet. Dr. Sondern has observed fifteen cases in children and adults in which the bacteriological examination of the throat demonstrated the bacillus and spiral of Vincent's disease, and the blood showed a very high grade of lymphocytosis. In fact, in cases which were clinically diagnosed as acute lymphatic leukemia and were subsequently investigated with especial reference to the throat, the bacillus and spiral of Vincent were found in the large majority of cases (15 cases). These highly interesting observations call for further study. They seem to me to be highly suggestive in demonstrating the connection between a peculiar throat infection and leukemic disease. On searching the literature I find a similar case published by Beltz,[3] from Fridrich Müller's Klinik (Case VII). This was a case of Vincent's angina, with an apparent acute lymphatic leukemia. The study of the organs, however, showed a myelogenous metaplasia. The author is therefore inclined to consider it a case of myeloblastic leukemia.

Acute Lymphatic Leukemic Disease; a Clinical Form of Infection of Mild, Severe, and Fatal Type.—Above we touched upon the subject of lymphocytosis as a specific positive chemotactic reaction, against certain well-known infective agents. We ascribed this phenomenon to which all infected subjects react in the same manner to certain properties of the pathogenic germs which come into play. I will now deal with a group of infections accompanied by a remarkably high lymphocytic blood count, often identical with the leukemic lymphatic blood count. Surprisingly little is known of this phase of the subject, either because the condition is rare, which is not unlikely, or perhaps because little attention has been paid to the subject. These infections are caused by the ordinary germs of catarrhal or purulent inflammation; they are the well-known infections which nearly invariably go hand in hand with the ordinary polynuclear leucocytosis. Richard C. Cabot[6] has described some of these cases under the heading of "The lymphocytosis of Acute Infection." Clinically they may appear under the guise of an ordinary wound infec-

tion, an angina, or enteritis. They are accompanied by a swelling of the spleen, liver, and lymph glands and by high temperature. Kothe reports cases of appendicitis with a very high lymphocytic blood count from Sonnenburg's clinic. Dr. Chas. A. Elsberg was kind enough to report to me two such cases. Evidently certain individuals in attacks of appendicitis and other enteritic infections react by a very high lymphocytic blood count. This fact is not generally known.

A short time ago, the following remarkable case, which at first looked like an ordinary head cold, came under my observation: Male child, seven years old; only child. Mother has chronic hyperthyroidism. Child is subject to head and chest colds. Large lymphatic tonsils at birth. Tonsillotomy and removal of adenoids at five. Vaccination when six months. Measles at four. Pertussis soon after. Milk grade of anemia. Differential blood count normal when in good health.

Present history: All members of household have colds. Patient has head and chest cold. Remittent temperatures 101° A.M., 101°-103° P.M. Enlargement of spleen, continuous, rapid. Liver can also be distinctly felt. Moderate swelling of lymph nodes all over the body, especially cervical and inguinal. At end of second week, lower border of spleen at niveau of navel. Marked prostration. Duration of illness three weeks. Blood examinations.

Day of Illness	Haemoglobin, per Cent	R.B.C.	W.B.C.	Polynuclears, per Cent	Small Lympho., per Cent	Large Lympho., per Cent	Transitionals, per Cent	Eosinophiles, per Cent	Basophiles, per Cent
7th	.....	.....	21,900	19½	65	12½	5	1	.....
9th	73	3,744,000	22,500	36	45	16	1⅔	1⅓	.....
12th	64	3,920,000	19,700	26⅓	62	8	⅔	3	.....
22nd	74	3,880,000	10,200	38	38	16	3	4	1

Remarks: Red cells show some irregularities in size and shape. They stain poorly. Widal test made on the seventh day of illness absolutely negative. Blood culture of same date also negative. Blood examination made some months after illness shows normal blood. During a severe cold, one year later, without fever, there were 6400 W. B. C., small lymphocytes, 21 per cent large mononuclears, 16 per cent. The blood was examined by Dr. A. L. Garbat. The case was twice seen in consultation by Dr. Isaac Adler.

This child was one member of a family, all of whom, at the same time had the usual winter's cold. The illness started in with rhinitis, pharyngitis, subsequently a light bronchitis developed. What first attracted my attention was the considerable and progressive swelling of the spleen, and the enlargement of the lymphnodes which was generalized. The blood was then repeatedly examined; the blood-picture was typical of an acute lymphatic leukemia in a child. It is true the degree of lymphocytosis was not that of a full-fledged case, but the condition having been discovered quite early it gave promise of developing into a fully developed acute lymphatic leukemia. Accordingly we were inclined to make a serious prognosis. However, the symptoms subsided, the lymphocytosis completely disappeared in the fourth week, as also the swelling of spleen, liver and lymph glands.

About the nature of the case, there can, I think, be but one opinion. To speak of it as a catarrhal fever with a severe lymphocytosis would not be an adequate description, or give to the case the distinction it merits. It was more than that. The case bore all the earmarks of an early stage of acute lymphatic leukemia. It ended in recovery. To designate it according to the usual clinical terms, we were dealing with a primitive or abortive type of acute lymphatic leukemia. Türk reports a small number of similar cases, which also occurred in children and young individuals. He speaks of these cases as representing examples of the "lymphocytic biological blood reaction." Inasmuch as these cases are due to an apparent infectious cause, and end in recovery, it is inferred that they are not cases of true leukemia. For so far the infectious origin of lekemia has not been demonstrable; the cases of cryptogenetic leukemia have invariably ended fatally. Long remissions may occur just as in anemia perniciosa, but the outcome is invariably fatal, except in one case of undoubted chronic lymphatic leukemia reported by Türk which has been well more than twelve years. Türk remarks: It is a question whether these cases of lymphatic reaction are identical with leukemia; but, he continues, they present the key to the whole question of the nature of leukemia.

In addition to these comparatively mild and typical cases, which clinically are analogous to, if not identical with what is usually looked upon as leukemia, there is a record of a considerable number of cases which clinically assume the form of sepsis associated with changes in the blood and tissues of a more or less typical leukemic character. The infective or septic nature is at once apparent. The course of the infection is also generally known, having entered by way of the mouth, throat, internal organs, bones, etc. Often to the surprise of the observer, a typical or atypical blood find is incidentally made. The combination of infection and leukemia is generally looked upon as accidental, and the observers are loath to accept the theory that the leukemia is the consequence of the infection—all the more so, as preliminary blood examinations before the advent of the present illness—are missing.

In the blood findings of the cases cited above there happens a rather sudden and increasingly complete absence of all but the smallest percentage of leucoytes, other than the lymphocytes, with the preponderance of the so-called large lymphocytes. Türk interprets these cases as a complete inhibition of the granulocytic elements (Verkeummerung des Granulocyteusystems). By that he means to imply that under the influence of the septic poison the myologenous tissues lose their ability to generate new cells, thus very few or none are thrown into the circulation, and complete lymphemia develops, and with that the power to cope with the infection ceases, and the patient dies of toxemia. I have gone very carefully over the protocols of the autopsies and the histological examinations of the tissues of the cases of this class. Each of these cases is a study. Any generalized statement as to histological findings would be incorrect. The findings vary according to the nature and the degree of the infection—the preponderance of the leukemic process in this organ or that, and lastly the effect of the mixed or terminal infection upon the blood forming and other organs. In a general way it may be stated that here, too, is found a uniform leukemic metaplasia pervading the tissues, just as in the cryptogenetic forms of the disease.

In this connection I may be allowed to cite a short history of a case—incomplete though it may be, which possibly belongs here, from Dr. Waldo's service in the Lebanon Hospital:

Young woman, family and personal history negative. One child living and well. No history of abortus. Menstrual history regular. Patient says that one week before admission she felt weak and chilly. She then noticed swelling of the face and gums. The last two days, bloody flow from the vagina. Examination: Swollen gums, enlarged glands of neck. Uterus not enlarged, no signs of extrauterine pregnancy. Blood exudes from the uterus. Pulse very rapid. Remittent temperatures for four days. Between the fifth and sixth day the temperature rises from 103° to 107°. Exitus. The following blood counts are significant:

On entrance:	
Hemoglobin	55 per cent
R.B.C.	2,690,000
W.B.C.	10,000
Polynuclears	75 per cent
Lymphocytes	25 per cent
Second blood examination:	
Hemoglobin	55 per cent
R.B.C.	2,500,000
W.B.C.	25,000
Polynuclears	3 per cent
Lymphocytes	97 per cent (mostly large)
Third blood examination:	
W.B.C.	30,800
Lymphocytes	99 per cent (mostly large)
Polynuclears	1 per cent

Status Lymphaticus and Acute Lymphatic Leukemia.—So far we have tried to indicate the influence of infectious processes in the etiology of leukemic disease, and although our knowledge of the cause, the immediate and remote effect of the pathogenic element upon the tissues is still disconnected and fragmentary, it now seems more than probable, that certain infections which ordinarily are accompanied by lymphocytosis, may exert an overwhelming lymphatic influence upon the affected individuals. There follows a suffundation of the tissues and generally of the blood too, by the lymphatic cells of various stages of development, and lymphatic leukemia results. And furthermore, it seems that the most ordinary bacteria, those causing the commonplace infections and suppurations, may, under peculiar circumstances, produce a lymphatic instead of a myelogenous blood reaction, a lymphotaxis, instead of a myelotaxis.

Now every individual being exposed at all times to the ordinary infections and very frequently also to the diseases accompanied by lymphocytosis mentioned above, the question naturally arises, what additional factor, exceptional though it may be, is necessary to initiate leukemic disease—which, after all is a comparatively rare affection. There must exist some basic condition in the leukemic individual, in all probability some inborn characteristics without which it is impossible for the leukemic disease to take root.

This theory seems especially plausible in acute leukemic disease, in which the symptoms of invasion become apparent at the turning of the hand. Acute lymphatic leukemia, the majority of which cases occur in the very young, calls for an inherent congenital disposition. Does this exist?

In his original description of lymphatic leukemia Virchow points to the conspicuous enlargement of the thymus. Since then we have learned, that in children, lymphatic leukemia, which is always acute in childhood, is regularly accompanied by thymic overgrowth and by considerable enlargement of the lymph glands of the neck, the submental and substernal region. In other words, acute lymphatic leukemia in children and young subjects is regularly grafted upon—the condition known as status thymolymphaticus. In the true interpretation of this fact lies, I think, the solution of the other half of the mystery of leukemia. Given a constitutional basis—in this instance the thymic or thymolymphatic state—then by the impetus of infection an overwhelming stimulation to lymphatic proliferation is created. We assume at the same time, with Türk, an inhibition of the myelogenous tissue reaction, partial or complete. The significance of this extreme aberrant reaction is not understood. It may be defensive in its nature. The system succumbs to the leucotoxic influence upon the blood and tissues, and to secondary or terminal infection.

From a clinical point of view, the importance of the recognition of the various forms of constitutional deficiency can hardly be over-estimated. The status lymphaticus is only one phase of developmental insufficiency of interest in this connection. Virchow taught us the significance of the hypoplastic constitution and the Vienna school of pathologists and clinicians, Rokitansky, Kolisko, Bartel, Neusser, and many others have worked out the various forms and combinations of constitutional deficiency which form the pathogenic basis of leukemic and other diseases hitherto wrapped in mystery. I mention this to indicate that in leukemic subjects other forms of constitutional deficiency have been found besides the lymphatic state.

The function of the thymus being unknown, the theory that in lymphatic leukemia a revivification of the thymus takes place is hypothetical. In the thymic state we do find a hyperplasia of the lymphatic tissue of that organ; in fact, the thymus may become very prominent and has often been looked upon as a tumor formation. What has been said above regarding the tumor conception of leukemic hyper- or metaplasia also applies to the enlarged thymus;[5] there is no reason why it should not be considered simply in the light of a hyperplasia of the lymphatic tissue, stimulated during the leukemic process by some infection. What interests us here specially is the influence of the thymus on tissue growth and blood formation (lymphocytosis), a question which is in the center of discussion at the present time, as regards the various aspects of thyroid disease. I will conclude by mentioning a very interesting clinical observation: the influence of revaccination in the pathogenesis of acute lymphatic leukemia. In the first case given in detail by Neusser,[9] there was a very strong general and local reaction, the lymphocytes ran up to 90 per cent. The same author describes another case after vaccination—with a sublymphemic blood count. Both individuals belonged to the hypoplastic type. Wilbur[7] describes a similar case. Evidently the patient belonged to the same class, having 54 per cent lymphocytes in 8800 leucocytes. One week after vaccination there were 252,000 leucocytes and 94 per cent lymphocytes, mostly large. The case ended fatally. We know that variola is regularly accompanied by a pronounced lymphocytosis. The pathogenic agent of vaccinia is probably also a lymphotactic germ. To sum up: The nature of lymphatic leukemia can best be studied not so much by means of the hematological method as from the broad standpoint of clinical observation and pathological research. Acute lymphatic leukemia is an infectious disease: It may develop as the result of infection by pathogenic agents, producing an overwhelming chemotaxis of a lymphocytic nature. But it can also be produced by the staphylococcus and streptococcus, and other pathogenic germs in individuals belonging to the thymolymphatic type and other forms of constitutional deficiency.

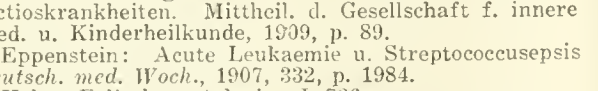
FURTHER OBSERVATIONS ON THE VALUE OF SCARLET RED IN THE TREATMENT OF GASTRIC AND DUODENAL ULCER.*

BY JULIUS FRIEDENWALD, M.D.,
PROFESSOR OF GASTROENTEROLOGY,
AND
T. F. LEITZ, M.D.,
ASSOCIATE IN GASTROENTEROLOGY,
UNIVERSITY OF MARYLAND SCHOOL OF MEDICINE AND COLLEGE OF PHYSICIANS AND SURGEONS, BALTIMORE, MD.

IN a paper published two years ago[1] we reported the result of treatment of thirty-seven cases of peptic ulcer with scarlet red, advocating the use of this drug not as displacing the time-honored rest cure treatments of Leube or the more recent cure of Lenhartz, but simply recommending its employment as a useful adjuvant in the treatment of this affection.

In this paper we noted the fact that John Staige Davis was the first to suggest the use of this drug in the treatment of ulcer of the stomach and to prove its usefulness experimentally in animals.

"Scarlet red has the scientific name tolueneazotolueneazo-betanapthol and is made by a combination of amidazotoluol and betanapthol and has the formula,



(Beta).

It is a reddish-brown powder and gives a scarlet red color in oil solutions. The powder as well as the oil solution is tasteless. Scarlet red is insoluble in water, but is soluble in alcohol, ether, and olive oil."

Davis's conclusions as to the effect of this substance are as follows: "The dyestuff used in this series of experiments is not toxic and apparently has no deleterious effect on either dogs or rabbits. When given by the mouth it is a fat-selecting vital stain. In the course of months the stain is gradually eliminated. Subcutaneous and intraperitoneal injections stain only the fat in actual contact with the scarlet-red oil solution. It is difficult to say from these operative experiments whether the scarlet red has, or has not, a definite stimulating action on the epithelium of defects in the gastric mucosa. However, the scarlet-red oil solution caused a more rapid and better developed growth of epithelium in the group in which it was used than occurred in the duplicate group where plain olive oil was used.

*Read at the annual meeting of the Medical and Chirurgical Faculty of Maryland, April 26, 1916.

The results with dry powder were not so favorable experimentally, but this may have been due to the fact that the material was not continuously in contact with the denuded area. We were unable to determine the relative effect of the scarlet red on chronic gastric ulcers, as it was impossible to produce chronic ulcers in dogs with controls of exactly the same size. Our experiments are suggestive, and, as this dyestuff may be safely administered, we feel that it is worthy of a thorough clinical trial."

According to our observations scarlet red may be administered in doses of from 15 to 20 grains, three or four times daily, without producing the slightest toxic effect, provided a pure preparation be employed (Biebrich). It is best given in 7½-grain cachets, 2 of which may be taken three or four times daily before meals. It may, however, be administered in much larger doses, and only after very large continuous doses can the odor of camphor be detected in the urine. Not the slightest toxic effect of this drug could be observed in any instance during its employment in over one hundred patients.

We reported the results of treatment of thirty-seven cases of ulcer in which scarlet red was employed in the course of treatment. In the largest proportion of these cases a most beneficial effect seems to have been obtained from its use. From the use of the remedy the following conclusions were drawn:

1. Scarlet red is a useful adjuvant in the treatment of peptic ulcer.

2. While it cannot replace the usual forms of treatment, when it is administered in conjunction with them it frequently renders the cure more effective.

3. As a help in the treatment of ambulatory cases it is of great service, and its effect seems to be even more favorable than that obtained from bismuth.

4. Its use need not in any way interfere with the administration of other remedies, such as the alkalies or belladonna, when indicated, and, in fact, the effect of the combination is at times most beneficial.

Since this publication, the use of this remedy has been noted by other observers. Zeublin[2] found it of value in a case of gastric ulcer with hemorrhage. Einhorn[3] points out its use in gastric and duodenal ulcer and Jones[4] has employed it along with the duodenal tube feeding, a daily dose of scarlet red in capsule being given by mouth, along the side of the tube with apparently good results.

We have since employed this remedy in forty-five more cases of ulcer with equally favorable results. As in the last report we have not included those cases in which the Leube or Lenhartz cure had been undertaken and which have made uneventful recoveries, inasmuch as most of such cases would have recovered without the help of any drug whatsoever; but have included only those in which the result of the rest cure was unsatisfactory and have added the ambulatory cases of ulcer, which remained unbenefited by the usual treatment.

Of these cases in which the remedy was employed sixteen were treated by the Leube rest cure, eighteen by the Lenhartz treatment and eleven were ambulatory cases. Of those treated by the Leube cure thirteen or 23.8 per cent. were cured; two or 4.4 per cent. were relieved and one or 2.2 per cent. was not relieved. Of those treated by the Lenhartz method fourteen or 31.1 per cent. were cured; two or 4.4 per cent. were relieved and two or 4.4 per cent were not relieved. Of those given ambulatory

treatment four or 8.8 per cent. were cured; four or 8.8 per cent. were relieved and three or 6.6 per cent. were not cured.

When we consider the fact that all of these cases resisted the usual treatment (that is, were treated by the usual methods first and were not relieved until the scarlet red had been administered), the result is most encouraging. The results obtained are much like those noted in our first report.

The results of treatment in the forty-five cases in which scarlet red was utilized are illustrated in the accompanying table. In it are noted respectively the location of the ulcer, the dose of scarlet red administered, the duration of treatment and its effect.

TABLE ILLUSTRATING THE EFFECT OF SCARLET RED IN THE TREATMENT OF FORTY-FIVE CASES OF PEPTIC ULCER

No.	Name	Age	Sex	Diagnosis	Form of Treatment	Dosage in Grains per Diem	Duration of Treatment in Weeks	Results
1	J.S.	22	M.	Duodenal	Leube	45	4	Cured

34	S.V.	37	F.	Duodenal	Lenhartz	60	3	Cured
35	B.B.	68	M.	Duodenal	Lenhartz	45	4	Cured
36	G.K.	44	M.	Duodenal	Leube	40	6	Cured
37	L.G.	47	M.	Gastric	Ambulatory	40	2	Cured
38	K.B.	52	M.	Duodenal	Lenhartz	60	4	Relieved
39	J.S.	38	F.	Gastric	Ambulatory	45	7	Not relieved
40	M.R.	62	M.	Duodenal	Lenhartz	60	6	Cured
41	F.S.	56	F.	Gastric	Leube	45	8	Relieved
42	O.P.	29	M.	Gastric	Ambulatory	45	4	Cured
43	N.K.	31	M.	Duodenal	Leube	40	4	Cured
44	B.C.	43	F.	Duodenal	Ambulatory	60	6	Relieved
45	C.F.	25	M.	Duodenal	Lenhartz	45	7	Cured

From our experience with this remedy in the treatment of the forty-five cases of peptic ulcer just noted, together with the results in the thirty-seven cases already reported, we believe we are justified in drawing the following conclusions:

1. Scarlet red still remains a useful adjuvant in the treatment of peptic ulcer and while it cannot by any means replace the usual forms of treatment, when administered in conjunction with them, it adds materially to the effectiveness of the cure.

2. It is of great help when administered in the ambulatory cases, the effect being even more favorable than the usual remedies, such as bismuth.

3. Inasmuch as scarlet red in no way interferes with the administration of other remedies, such as the alkalies or atropine, these may be administered when indicated at the same time and in fact, the effect of the combination is at times most beneficial.

A STUDY OF THE NORMAL BACTERIAL FLORA OF POSTAGE STAMPS.

BY ROBERT A. KEILTY, M.D.,
AND
MR. PHILIP D. McMASTER,
PHILADELPHIA, PA.
(From the McManes Laboratory of Pathology, University of Pennsylvania.)

THE purpose of this study was to determine the normal bacterial flora of postage stamps, that is, to get some idea of the general character of bacteria found on stamps with especial emphasis in the search for tubercle bacilli, *Bacillus tetani*, the colon group, and diphtherial forms.

The literature on this subject is surprisingly meager and but little record is made of the bacteria of stamps. The subject is usually approached from the viewpoint of the spread of infection by the postal service as a whole, the infection by letters and the fumigation of letters, and but little record is made of infection by stamps or of the bacteria of stamps.

In order to determine this fifty stamps were bought in various stores in Philadelphia, including the central office, branch offices, almost all the large department stores, many drug stores, and some of the small general stores. Most of the stamps were bought from sheets and a few (3) from stamp books. The character of the place was noted, its general cleanliness, the clerk and his appearance, and whether the stamps were placed on the counter with the change or not. In almost all cases they were presented with the glue side up showing that the precepts of public hygiene have had this much effect.

The clerk was then asked to place the stamp in a sterile tube in which it was taken to the laboratory. Each stamp was then smeared over blood serum, agar, and a bouillon tube was inoculated and finally, incubated in sterile water in a centrifuge tube for twenty-four hours. This was centrifuged and the sediment used to inoculate tubes of bouillon, Petroff's medium, and smears made and stained for the tubercle bacillus.

The first fifteen stamps were treated in this manner, and among other growths, two which appeared to be *Micrococcus aureus* were obtained, but as it was believed that many more like these would be found their pathogenicity was not tested. It later appeared that on the remaining thirty-five stamps no similar growths were found.

The other thirty-five stamps were treated in a different manner. Each was cut in half, one-half treated as were the first fifteen smeared on blood serum, agar, and in bouillon, then centrifuged in sterile water and the sediment used to inoculate Petroff's medium, bouillon and smeared on slides which were stained for the tubercle bacillus. The other half was incubated in a centrifuge tube with 3 per cent. sodium hydrate for twenty minutes, neutralized with normal hydrochloric acid and centrifuged. The sediment was used to inoculate tubes of Petroff's medium and smeared and stained for tubercle bacillus. This method rendered two smears stained for tubercle bacilli, two tubes of Petroff's

medium and five of the ordinary media for each stamp.

Concerning the growths found; all were negative with respect to tubercle bacilli, colon and diphtherial forms. A surprisingly small number of moulds were found, only six in all, with practically the same number of *Bacillus subtilis*. A great number of non-pathogenic cocci were found of which a large light yellow form and a small white glistening form were most common. The pathogenicity of these was tested in guinea pigs and found to be negative, not even producing a swelling at the site of inoculation. From their cultural characteristics they were believed to be *Micrococcus citreus* Sternberg or *M. flavus* Flugge and *M. dissimilis* or *M. descidens* for the small white form. Other micrococci were found, small yellow forms which were non-pathogenic and from their cultural characteristics and behavior were believed to be *M. luteus* and *M. versicolor*.

Five rod forms were obtained but these were found to be of only two different forms, one a long slender curved organism, the other a shorter and broader form. These were found to be non-pathogenic for guinea pigs. It is interesting to note that two stamps were found to be completely sterile.

A summary of the results giving the probable kinds of organisms found is as follows:

Micrococci 53
- White 33
  - small 22 — *M. dissimilis* / *M. decidens*
  - large 11 — *M. candidus* or *candidans*
- Yellow 16
  - small 6 — *M. luteus* / *M. Versicolor*
  - large 10 — *M. citreus* Sternberg / *M. flavus* Flugge

Micrococcus aureus, possibly two growths.
Micrococcus aurantius, one.
Moulds, six.
Bacillus subtilis, four.
Percentages:
Micrococci (non-pathogenic), 81.
Moulds, 8.
B. subtilis, 5.5.
Other bacteria (non-pathogenic), 5.5.

The majority of the stamps showed one or more organisms but in no single instance were they found to be pathogenic in type. This does not exclude the fact, that under favorable conditions certain pathogenic types, which would resist drying to a certain extent, might not be carried on a postage stamp. On the other hand the work proves the stamp to be a carrier of organisms and these could readily be transferred from one individual to another. This would only be of importance where the organism was pathogenic. We have in mind a drug store where one of the members of the druggist's family had advanced tuberculosis. His sputum as well as his feces contained may bacilli, he had a hacking cough and was in the habit of protecting his mouth with his hand while coughing. During busy times he often served customers, and not infrequently dispensed stamps to children who would immediately moisten them with their mouths and paste them to letters. A single exposure in this case might prove negative, but the constant exposure in some cases would undoubtedly end in infection.

We are in debt to Mr. H. McC. Miller for much valuable assistance in the routine work of this paper.

Conclusions.

1. A study of fifty stamps obtained from as many different sources, clean, dirty and indifferent, showed bacteria in every instance except two.

2. With the possible exception of two cases no organism pathogenic in type was encountered.

3. Aside from hygienic reasons it is dangerous to lick postage stamps on the ground that the stamps are bacteria laden and under favorable conditions might easily convey pathogenic types, especially colon, diphtheria and tubercle bacillus.

4. We would therefore advocate a movement to have installed in all places dispensing postage stamps a moistening device of some type. This movement could be started with beneficent results in the post-offices of the United States Government.

Medicolegal Notes.

Incompetent Hypothetical Question—Whether Accident Caused Disease.—In an action for injuries received in a street car collision, claimed to have resulted in a tumor on the breast and traumatic neurasthenia, an expert witness for the plaintiff was asked: "Doctor, referring to the suppositions or hypothetical patient and taking into account the elements of the hypothesis, have you an opinion, as a medical man, and based upon reasonable certainty, as to what was the cause of the neurasthenia and the tumor in the hypothetical patient?" A.—"Yes, sir." Q.—"What is your opinion as to the connection between this disease and the tumor or growth in the breast?" A. "That the tumor resulted from the bruise—the injury to the breast. The neurasthenia resulted from the shock of the accident, and was kept alive by the breast condition." The Illinois Supreme Court held that the questions were improper, as invading the province of the jury and calling for an opinion on an ultimate fact. Where there is a conflict in the evidence, as in this case, as to whether or not the party suing was injured in the manner charged, it is not competent for witnesses, even though testifying as experts, to give their opinions on the very facts the jury is to determine. Whether or not the collision in this case caused traumatic neurasthenia in the plaintiff or caused the tumor in her breast were ultimate facts upon which the jury must make their findings. It is no more proper legally for physicans to settle these questions for the jury by their direct answers than it would be for a motorman of another street-car company to settle the question of negligence by testifying in broad terms that the defendant was guilty of negligence because the motorman failed to cut off the power by use of the canopy switch in time to prevent the collision. The rule in such cases is not different where hypothetical questions are put to the expert witnesses. A physician may be asked whether the facts stated in a hypothetical question are sufficient to cause a certain condition, or he may be asked whether a given condition may be caused by the facts stated in the hypothetical question. But he should not be asked whether or not such facts did cause such condition or malady. In cases where there is no dispute as to the manner and cause of the injury, and no dispute that there was an injury sustained by reason of the acts of which compaint is made the Illinois Supreme Court has held that a physician may then testify that a later malady was or was not caused by the accident or original injury, upon the same principle that he may testify that death resulted from a certain wound. The physicians having stated that the plaintiff's tumor and neurasthenia were caused by the collision, the jury had to award large damages under this evidence. Judgment for the plaintiff was reversed and a new trial granted.—Fellows-Kinbrough v. Chicago City Ry. Co. (Ill.) 111 N. E. 499.

Malpractice—Evidence.—In an action for malpractice in diagnosing and treating the plaintiff's dislocated shoulder as a sprain, the evidence conflicted as to whether the defendant applied the usual tests by inserting the fingers in the armpit and placing the patient's right hand on the opposite shoulder with the elbow pressed against the side or chest. The injury was sustained on February 3, 1912, at which time the plaintiff alleged the shoulder was dislocated. It was held that evidence of physicans that they found on March 25 following that there was a dislocation was admissible when considered in connection with evidence of a sufficient cause of dislocation on Feb. 3, and the evidence of the plaintiff and his wife that the shoulder had suffered no injury between February 3 and March 25. It was held that the evidence of dislocation and of the defendant's failure to properly diagnose the case was sufficient to take the case to the jury.—Hoffman v. Watkins, Washington Supreme Court, 155 Pac. 159.

IS THE PRESENT ILL-REPUTE OF SPINAL ANESTHESIA DESERVED?

THE sudden vogue attained by spinal anesthesia several years ago is still fresh in our minds, but we search in vain for like popularity to-day. The method, in this country anyway, appears to have fallen into desuetude, in spite of the ardent claims formerly made for it. The reason for this abrupt decline from favor would probably be summed up by the average physician as three in number: Unreliability of action, disagreeable after-effects, and a high mortality. And yet we get reports from anesthetists who have used the intrathecal method in large numbers of cases which deny the first and the last of these reasons and report the second as practically negligible. The suspicion naturally arises then that perhaps some error of technique has been responsible for the lack of success reported hitherto.

Several hundred cases were reported by Dr. C. G. Holman in the *Lancet* for May 6, with no bad results other than severe temporary headache in a few cases, readily relieved by aspirin. Holman believes that novocaine is less toxic than stovaine, being led to that opinion by experiments which he made on rabbits; the maximum dose is 0.075 gm. Apropos of this dosage he comments on the fact that an example of the bad results published was in a case in which 0.15 gm. was given to a patient 68 years old. The position recommended by this writer is lying on the side with the knees drawn up and the back rounded. In the same periodical for June 10, Dr. Page, who not long ago reported a series of prostatectomies under spinal anesthesia, and Dr. Chapple speak a good word for this form of anesthesia in those cases where a more complete muscular relaxation is desired than can be obtained under the ordinary "deep" anesthesia, and where it is essential to minimize shock. Seventy cases of pelvic operations were reported with nine deaths, none of which could be attributed in any degree to the anesthetic. These were for the most part cases in which a general anesthetic was contraindicated—heart and kidney cases, alcoholics, excessively obese persons, etc. Dr. Page's practice was to put the patient in the Trendelenburg position after the injection of the anesthetic, a procedure which is not generally known in this connection. A complete flaccid paralysis of the lower half of the body was obtained, extending sometimes as high as the second rib; this disappeared shortly after the operation. Dr. Chapple, who did the operation in nearly all of these cases, remarks that some of the patients could not have been operated on at all except by this method. These writers also report an occasional headache lasting a short time.

With these favorable reports at hand, it would seem that a recasting of some of the opinions of spinal anesthesia currently held would be necessary. It is quite evident that the method should not be attempted except by one who is thoroughly versed in its technique, as an incorrect position of the patient, a failure to reach the spinal canal, a withdrawal of too much or too little fluid, an injection of too small or too large a dose, may cause either a failure to obtain anesthesia or collapse during the operation.

THE DISTRIBUTION OF TETANUS TOXIN.

IT is the general belief at the present time that tetanus toxin, elaborated at the point of infection and growth of the organism, passes up along the axis cylinders of the motor nerves to the central nervous system where it combines with the cells for which it apparently has a special affinity, and, as a result of this combination, changes take place which produce symptoms.

In the course of his extensive studies upon this disease, Robertson has devoted a certain amount of time to an effort to determine how the toxin is distributed in the body and how it makes its way from the periphery to the brain. He reasons very clearly (*American Journal of Medical Sciences*, clii, 1916, 31) that theoretically it is difficult to understand how tetanus toxin, which admittedly has a high degree of affinity for nerve cells, may travel along an axis cylinder without combining with it. The axis cylinder is merely the process of a cell, and logically the toxin would be expected to combine with it and therefore remain in place. He asks very pertinently if this is "a hitherto unknown affinity to travel?" He points, however, to the demonstration of lymph channels in the substance of nerve trunks, and records several of his own successes in injecting them. It is naturally difficult to trace them, for the usual methods of section and ligature of the nerve would, of course, obliterate the lymph channels, and moreover these spaces are blocked by degenerating myelin material whenever a nerve is cut. Given, therefore, the existence of this lymph stream, it would certainly be the natural path for the passage of any substance in fluid form. Robertson goes carefully into the experimental evidence on hand and shows that none of the results exclude the possibility of transmission in this way. He then cites some experiments of his own which he considers to have weight in the support of his side of the discussion.

The author of this interesting paper makes out a very strong argument. The theory which is now dominant has always been a difficult one to accept upon philosophical grounds, and Robertson's is much more plausible. There are still points which need elucidation, and it is desirable that the lymphatic

system be studied more intensively. Weed and Wegefarth have shown that the spinal fluid drains out, to a very slight extent, through the perineural lymph channels, but were unable to demonstrate any influx of fluid into the cerebrospinal cavity except from above. The existence of lymph channels within the substance of the nerves trunks and of a current in them carrying fluid toward the brain, is a fact of considerable importance if it can be fully demonstrated. It would be interesting to know the destination of this fluid, for it has been the experience of most investigators that very few substances find their way into the cerebrospinal fluid in spite of this apparently easy pathway. Thus this work is of considerable importance not only in its connection with the treatment of a dangerous disease but also because of its relation to the physiology of the nervous system.

A PHILANTHROPIC POSSIBILITY.

Probably we have all indulged in that most agreeable of all phantasies, the picturing of what we would do with boundless wealth. Some of us would erect model hospitals, some pattern medical schools, give scholarships to needy but earnest disciples of Æsculapius, send them abroad to study, etc., etc. Nevertheless it is sometimes very difficult to know just what to do with all of the unearned increment. After the organized charities have been appeased, the poor relatives made comfortable for life, and religious duties recognized, the question arises as to the proper disposition of the remaining thousands destined for charity.

Let us then suggest for the relief of these distressed millionaires a scheme by which they can help to reduce infant mortality at small cost. To explain it fully we must go back some ten years to the time when one Benjamin Broadbent was elected Mayor of the Borough of Huddersfield, England. Having always taken a strong interest in the problem of infant mortality, and having viewed with alarm its prevalence in his community, he offered a birthday gift to every child born within the village of Longwood, in his borough. This took the form of a promissory note for one pound sterling, payable when the child should become one year old. The natural consequence was that parents awoke to the fact that the survival of their babies depended somewhat on the care they received. Their pride and interest were aroused, and they determined to keep their children alive through that first year, not only because of the five dollars, although that was a large sum to many of them, but for the sheer sake of winning. Best of all, Mayor Broadbent's unique scheme attracted so much attention to the subject of infant mortality, especially in his own borough, that it became a kind of headquarters for the study of the subject.

Why, then, does not some philanthropist set in motion a similar scheme in some district in the United States where the mortality of babies is high? There is little doubt but that he would be doing good, and the only drawback to the proposition would seem to be the almost certain result that about 50 per cent. of the fortunate babies would bear their benefactor's name for life.

Twlight Sleep Again.

Little has been heard recently of that form of amnesic analgesia known as twilight sleep. It is only a few months ago when it was a fruitful theme for discussion, not only in medical journals but in the lay press. At first it was heralded, chiefly in magazines, as one of the most beneficent procedures ever introduced and its good features were so lauded out of all proportion that it was difficult to take an unprejudiced view of its distinctive points. However, one is able now to consider the method judicially and to pass upon the drawbacks or merits in a sane manner. In *Surgery, Gynecology and Obstetrics* for June, Dr. Charles B. Reed has a paper on the subject in which he reviews his experiences in the use of the method. He states that from observation of cases treated by himself and others the belief has been reached that the morphine-scopolamine analgesia is entirely harmless to both mother and child when properly administered. He regards the treatment as successful in his hands, since 29 per cent of his cases were practically, and 56 per cent entirely, free from pain, or 85 per cent in all. The strength is conserved and the convalescent period shortened. Whether or not the woman gets up earlier is a question of uterine involution rather than one of days or strength or treatment. The main thing is that she feels better much sooner. It is Reed's opinion that primary pain, weakness, hemorrhage, prolapsed cord, and a lack of correlation between the size of the pelvis and the child make conditions that are unfavorable for twilight sleep. He does not believe that twilight sleep can be produced in every case, but it does no harm, he says, when properly used and he is convinced it will act happily in about 85 per cent of the cases selected with due regard to contraindications. He regards it as a valuable and permanent addition to the resources of the obstetrician, and says that much of the antagonism to it arises from an inability or an unwillingness to bestow upon a woman in labor the unremitting attention and the higher technical proficiency which these cases demand. The above is interesting testimony in favor of a mode of overcoming some of the unpleasant features, notably pain, of parturition, and is not altogether in harmony with the experience of many other observers.

Spontaneous Chronic Nephropathy of the Dog.

Although chronic nephritis in the dog is quite a common disease, and the fact has been recognized by many investigators, nevertheless it has apparently been overlooked to a certain extent and no really adequate study of the subject has been undertaken. The matter is very important, for the dog is an easily obtainable animal which has been used largely for experimentation and the question of proper controls is an essential one. MacNider has undertaken an investigation of the subject and reports his findings in a recent paper (*Jour. Med. Research*, 1916, xxxiv, 177). Out of a total of two hundred and thirty-seven dogs, forty-two had constantly or intermittently an albuminous urine with various types of casts, and at autopsy showed unquestionable evidence of kidney injury which was farly diffuse in its distribution. Eighteen other animals showed localized areas of kidney injury but were excluded from this series. Of the forty-two animals studied, the changes in eighteen were confined very largely to the glomeruli. In the remainder the changes were of the same type but in a more advanced stage. In several there was sclerosis of

the renal arteries. No acute inflammatory changes were observed. There was apparently very little effect upon the tubular epithelium. When these animals were made acutely nephropathic by uranium it was found that the action of the drug was practically the same as upon the normal kidney while the regenerated epithelium which was formed in the course of healing of a uranium nephritis was more resistant to the action of this drug than was normal epithelium. The work is very interesting and the article will bear careful study. Careful controls are even more essential in animal experimentation than in many other varieties of research and in this special instance the controls are apparently rather difficult to obtain.

Visceral Inversion.

So-called heterotaxia has now been placed on record at least 170 times. Many cases are autopsy finds, while of the clinical material not much has been radiographed. Simple dextrocardia is extremely rare and has been encountered as a familial affection. Much the greater part of the material is made up of complete heterotaxia. Electrocardiograms have been obtained in both forms, naturally accompanied by skiagrams. A. de Castro of Rio de Janeiro with two colleagues has been able to place on record three cases of complete heteroataxia within a very brief period. This would of course suggest that the condition cannot be so very rare (*Archives des maladies du cœur, etc.*, May, 1916). All three subjects had pulmonary tuberculosis. The heart's action was normal (in simple dextrocardia, on the contrary, the heart's action shows modification). In none of the patients was there evidence of morphological anomaly of any sort. All of them were right handed. The spleen could be recognized on the right by physical exploration. In one of the patients the heart, stomach, liver, and spleen were transposed, but not the intestine.

News of the Week.

The Poliomyelitis Epidemic.—There has been a progressive increase in the number of new cases in this city during the few days preceding the present writing, but it is hoped, nevertheless, that the height of the epidemic has been reached. The total number of cases reported up to July 20 is 2,327, the deaths being 455. Dr. C. E. Banks of the United States Public Health Service has been ordered here from Milwaukee to take charge of the work for prevention of the spread of the disease outside of the city. The Rockefeller Foundation has donated $50,000 to aid in the work of discovering and keeping under observation suspected carriers of the disease. Dr. Alvah H. Doty, former quarantine officer of the port of New York, has been appointed administration officer in charge of this work and he has under him a considerable staff of physicians and nurses. The laboratory investigations are under the supervision of Drs. Lavinder and Frost of the U. S. Public Health Service. The use of adrenalin, as recommended by Dr. Meltzer at the special meeting of the Academy of Medicine on July 13, a report of which is presented on page 167 in this issue, has been tried this week with apparent success in a number of cases at the Throat, Nose and Lung Hospital. The remedy was given in 2 c.c. doses every six hours, and was followed by marked improvement in the paralysis as well as in the general condition.

Cuban Quarantine Against the United States.—The Cuban sanitary authorities have adopted quarantine restrictions against United States children on account of the epidemic of infantile paralysis. In the future children arriving from American ports who have an abnormal temperature will be isolated until the trouble is diagnosed, while children in normal health will be kept under surveillance until the danger of developing infantile paralysis has passed.

Poliomyelitis Clinics.—The Department of Health, through the cooperation of various hospitals which are treating a large number of cases of poliomyelitis, has arranged a series of clinical lectures to physicians. These clinics are to be conducted during the week commencing Monday, July 24, at the following hospitals: *Willard Parker Hospital*—Dr. Philip Van Ingen and associates, 4-5 P. M., Monday, Tuesday, Wednesday, Thursday, and Friday. *Kingston Avenue Hospital*—Dr. Louis Ager and associates, 4-5 P. M., Monday, Tuesday, Wednesday, Thursday, and Friday. *Mt. Sinai Hospital*—Dr. Herman Schwarz, 4-5 P. M., Monday, Tuesday, Wednesday, Thursday, and Friday. *Bellevue Hospital*—Dr. J. S. Ferguson, 4-5 P. M., Tuesday, Thursday, and Saturday. *Babies' Hospital*—Dr. Charles Gilmore Kerley, 4.30-5.30 P. M. Tuesday and Thursday. *Swinburne Island*—Dr. Frank Clark, 4-5 P. M., Thursday and Friday.

New York State Commission for Boy Training.—At the recent session of the Legislature of this State a bill was passed providing for physical training of not less than twenty minutes each day by all pupils eight years of age and over in the public and private schools in New York State. The program to be followed is to be determined by a commission composed of the Major General commanding the National Guard (Gen. John F. O'Ryan), a member appointed by the Board of Regents of the University of the State of New York, and one appointed by the Governor. The choice of the Regents fell upon Dr. John H. Finley, Commissioner of Education, and the Governor has appointed Dr. George J. Fisher chairman of the Committee on Awards and Scout Requirements of the Boy Scouts of America.

Prize for the Best Artificial Hand.—The Royal Surgical Society of London, according to *The Sun*, has received a gift of a large sum of money to be offered as a prize to the inventor of the best artificial hand. Competitors will have to exhibit persons who have worn the hands for at least six months.

The American Field Ambulance in France, which now has 150 cars in service, has been made an independent unit and separated from the ambulance organization at Neuilly. A. Piatt Andrew will continue as chief inspector and will be assisted by Stephen Gallatin of New York. Of the cars now in service 125 are on the Verdun front. New cars are being fitted out, and young men are coming from the United States to drive them, so that by the end of August 200 cars will be in service, or five times as many as a year ago. The Field Ambulance will have a suburban villa, where the drivers can rest when on furlough.

Death of the Kaiser's Laryngologist.—It is reported from Amsterdam that Dr. Friedrich W. K. von Ilberg, to whose care was intrusted the management of the chronic throat affection from which the German Emperor suffers, died in Berlin on July 9.

American Hospital Unit in Bohemia.—The

American hospital unit, consisting of four surgeons and four nurses from the American Physicians' Relief Association, has been assigned to Pardowitz, Bohemia, where one of the largest and most up-to-date hospitals in the empire, with a capacity of 10,000 patients, is located. The surgeons are Drs. Martin, Moore, Corby, and Mincke.

Another Red Cross Hospital Ship Torpedoed.—The National Headquarters of the American Red Cross in Washington announces that they have just received the following cablegram from the Central Committee of the Russian Red Cross in Petrograd: "On July 8 about 9.00 o'clock in the morning the hospital ship *V"Peryod* of the Russian Red Cross having all the external marks required by the Hague Convention was torpedoed and sunk about thirty-two leagues from Batum, near the village of Vitse (on the Black Sea) by an enemy submarine. There were eight deaths and seven wounded among the crew and sanitary personnel of the ship. All hostile governments had been notified of the equipment of the *V"Peryod* as a hospital ship. All possibility of a mistake is excluded. We protest with most profound indignation against this new crime."

American Physicians Wanted in London Military Hospitals.—Sir William Osler has sent word to a number of American surgeons that there are vacancies for 120 young American medical graduates in the military hospitals of London and its immediate neighborhood. The term of service is six months. There will be a small salary and passage will be paid both ways. Applications will be received by Dr. Richard Cabot and Dr. Henry A. Christian of Boston; Dr. W. S. Thayer of Baltimore; Dr. Dean Lewis of Chicago, and Dr. Karl M. Vogel, 437 West Fifty-ninth Street, New York.

Another Base Hospital Unit for the Mexican Border.—The American Red Cross Headquarters announce that a base hospital unit at the German Hospital in New York is being organized under the American Red Cross. Its director is Dr. Frederick Kammerer, who has just withdrawn from active service with the German army and brings to his new task the very valuable knowledge gained at the German front in the European war zone.

Camps for Medical Men at Plattsburg.—Major General Leonard Wood, commanding the Eastern Department of the Army, has announced that two training camps for medical men will be held in connection with the regular Plattsburg Military Training Camp this month. The first camp began on Wednesday and the second will begin on July 24. The course of instruction will emphasize camp sanitation and military hygiene. The camps will be commanded by medical officers of the regular army. Psysicians desiring to attend one or both of these camps should communicate with the Military Training Camps Association, 31 Nassau Street, where enlistment blanks will be furnished on application.

Goggles for Troops in Texas.—Mr. Oliver Iselin has sent a check to the Red Cross to pay for goggles for use by the New York National Guard on duty on the Mexican border to protect them from the alkali dust and glare of the sun.

Dr. Cecil D. Gaston has been elected by the Jefferson County Medical Society health officer of the city of Birmingham, Ala. Dr. Gaston has served as city physician for several months. He is a graduate of Jefferson Medical College, Philadelphia.

Dr. Franklin C. McLean, assistant resident physician in the hospital of the Rockefeller Institute, New York, has accepted an appointment by the trustees of the Union Medical College, Pekin, to the professorship of Internal Medicine. The appointment carries with it the headship of the Union Medical School. This is one of the institutions of the China Medical Board of the Rockefeller Foundation.

Mr. Hardolph Wasteneys, associate in the Department of Experimental Biology in the Rockefeller Institute, New York, has accepted an appointment as associate professor of pharmacology in the University of California.

A Symposium on Acidosis.—The June number of *American Medicine,* recently issued, is devoted largely to papers dealing with acidosis in its various aspects, the contributors being some of the best known clinicians and laboratory workers in this country and Great Britain. Among them are P. J. Cammidge, Eric Pritchard, Frederick Langmead, Herbert Williamson, and Edward Gillespie of London, England; Robert T. Morris, Heinrich Stern, Robert Coleman Kemp, Anthony Bassler, A. C. Burnham, William P. Cunningham, George Dow Scott, Louis Fischer, Samuel Floersheim, and John W. Wainwright of New York; George W. Crile of Cleveland, Alfred C. Croftan and Bayard Holmes of Chicago, J. H. Kellogg of Battle Creek, Stephen H. Blodgett of Boston, and W. S. Gordon of Richmond, Va. It is unusual for a single issue of a journal to contain so many notable contributions, and the editor, Dr. H. Edwin Lewis, is to be congratulated upon having produced such an interesting and instructive contribution to the literature of this very live subject.

Kentucky Valley Medical Association.—At the annual meeting of this association, held at Richmond, Ky., June 29 and 30, the following officers were elected: *President,* Dr. Clarence H. Vought of Richmond; *Viee-President,* Dr. Wilson Bach of Jackson; *Secretary-Treasurer,* Dr. J. H. Evans of Beattyville.

The Connecticut State Board of Health, at a recent meeting in Hartford, re-elected its present officers as follows: *President,* Dr. Edward K. Root, Hartford; *Secretary-Treasurer,* Dr. John Torrington Black, New London; *Sanitary Engineer,* J. Frederick Jackson, New Haven; *State Baeteriologist,* Prof. H. W. Conn, Middletown.

The American Association of Immunologists.—At the recent meeting of this association held in Washington, D. C., May 11 and 12 the following officers were elected: *President,* Dr. Richard Weil, New York; *Viee-President,* Dr. John A. Kolmer, Philadelphia, Pa.; *Treasurer,* Dr. Willard J. Stone, Toledo, Ohio; *Secrtary,* Dr. Martin J. Synnott, 34 South Fullerton Avenue, Montclair, N. J.; *Council* (1918), Dr. William H. Park, New York; (1921), Dr. Arthur F. Coca, New York.

The Status of the Officers of the American Medical Association.—Quo warranto proceedings were filed recently by Illinois State's Attorney Horne seeking to declare the charter of the American Medical Association forfeited in consequence of the holding of elections elsewhere than in the State of Illinois and of denying to the fellows of the Association the right to vote for officers.

Obituary Notes.—Dr. FRANCIS SORREL, formerly of Savannah, Ga., died at his home in Washington, D. C., on June 30, at the age of 89 years. He was born in Savannah and was graduated from the Uni-

versity of Pennsylvania in the class of 1848. He was in the medical corps of the U. S. Navy from 1849 to 1856, when he retired from the service and began practice in Savannah. During the Civil War he served as surgeon with the Georgia troops, and in 1865 was appointed medical director of the General Hospital in Richmond, Va. At the end of the war he returned to Savannah and lived there until two years ago, when he went to Washington.

Dr. THOMAS A. ASHBY of Baltimore, Md., a graduate of the University of Maryland, School of Medicine, Baltimore, in 1873, a member of the American Medical Association, the Medical and Chirurgical Faculty of Maryland, the Baltimore City Medical Society, and the American Gynecological Society, and a fellow of the American College of Surgeons, died at his home, after a lingering illness, on June 26, aged 67 years. Dr. Ashby was the founder of the *Maryland Medical Journal*, and its editor from 1877 to 1892, and had been professor of gynecology in the University of Maryland since 1897.

Dr. ARCHIBALD M. GLASS of Booneville, Ky., a graduate of the University of Louisville, Medical Department, in 1885, and a member of the American Medical Association, the Kentucky State Medical Association, and the Owsley County Medical Society, of which he was secretary for some years, died at his home after a long illness, on June 21, aged 53 years.

Dr. JAMES T. ROAN of Wayness, Ga., died at Jones, near Savannah, on June 30, at the age of 64 years. He was a graduate of the Southern Medical College, Atlanta, in the class of 1882. He had been in ill health for several years.

Obituary.

ELIE METCHNIKOFF, M.D.

PARIS, FRANCE.

PROFESSOR ELIAS METCHNIKOFF, the last of the pioneers in bacteriological science, died of heart disease on Saturday in the Pasteur Institute, Paris, at the age of 72 years. He had been ill for several months, and his death had been expected momentarily. He was born in Russia May 16, 1844, and began his scientific career as a naturalist. It was while studying cellular embryology in the young of marine organisms that he discovered the phagocytic action of the leucocytes. From this followed his theory of inflammation that the hyperemia and pus formation were due to the rush of the leucocytes to the injured part in their effort to destroy the invading microorganisms. His theory of immunity was also based upon this discovery, the antibodies being products of the attacking leucocytes. He came from a short-lived family, and this fact turned his attention to the subject of longevity, from which followed his theory of the intestinal origin of arterial and other degenerations which shorten life and of the action of the lactic-acid bacilli in destroying the noxious intestinal flora.

He entered the Pasteur Institute in 1888, and in 1895 was appointed its director. The Nobel prize in medicine was awarded him in 1908. It is impossible in a short notice to recount all that Metchnikoff has done for science, for he was working productively in this field for forty-five years, and will rank with Pasteur, Lister, Ehrlich, Behring, and Koch as one of the giants in the practical application of bacteriology to the saving of human life.

Correspondence.

THE TREATMENT OF INFANTILE PARALYSIS.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In the discussion following the papers on infantile paralysis read at the special meeting of the Academy of Medicine on July 13, I made some remarks which were reproduced in the daily press. This brought results which compel me to ask you for some space in your journal. In the first place I am receiving many letters, telegrams, and telephone messages asking for exact information as to how to use adrenalin, etc., and would therefore request you to publish an exact reproduction of my remarks which I purposely read from notes. [See under the report of the meeting of the Academy of Medicine, pages 171 and 172.]

Regarding the two apparatuses mentioned, I expect to publish soon a detailed description of both of them and their working. However, I wish to add that I would gladly demonstrate the action of these apparatuses at the Rockefeller Institute if there should be a number of physicians who would signify their desire to witness such experiments; a definite appointment could then be arranged.

As I have said, the metropolitan press took notice of my statement regarding the use of adrenalin in infantile paralysis. This was resented by the Health Department. "The medical importance of this is not so great as the space in the newspapers would indicate." " . . . his (Dr. Meltzer's) suggestion was purely theoretical." "It is unfortunate that the newspapers have seized on this one small detail." While I am confident that Dr. Emerson, who is an old friend of mine, did not intend to offer an affront to me personally, or to suppress the use of adrenalin in the treatment of infantile paralysis, the undertone of the various statements emanating from him as well as from Dr. Ager could not fail to discredit the value of my suggestions and to imply that I have been guilty of some impropriety. Permit me to deal here with both points in question. In the first place, as to the propriety of my actions. I received a call at my house from two competent physicians from the Kingston Avenue Hospital who wished to learn my views of the treatment of poliomyelitis. I spoke to them at length and promised to bring out the two respiratory apparatuses to the hospital and to demonstrate their use. Next morning I called up Dr. Emerson to find out whether my going there would meet with his approval and asking him at the same time to exert his influence that my activities there should not be ventilated in the public press. I then learned that there would be a meeting of the Academy of Medicine which would deal with infantile paralysis. I asked the president to put me upon the list of those who would discuss the papers. At the meeting I found that anything I wished to say had to be within five minutes or less. As the last participant in the discussion of that meeting I had to speak very briefly, but I spoke as a medical man, on a medical subject, to a medical audience. I was certainly within my rights. I could not be held responsible for the fact that the newspapers thought that what I said was worth a wide circulation. I gave no interviews.

Now, as to the merits of the treatment. The first requirement of a new treatment is that it should do no harm. On the basis of my extensive experi-

ence I was, and am, sure that a cautious intraspinal injection of adrenalin does no harm. As to the good it may do, I have given in my brief statement full reasons for the justification of my expectations. Will adrenalin accomplish a real cure? Anyone who is trained in experimental and clinical criticism can readily see that this question can not be answered for some time to come. On the one hand, it is quite certain that in many cases it will be of no value on account of the frequent occurrence of a steady ascending progress of the chief inflammatory focus to the origin of the phrenic nerves and to the respiratory and the vasomotor centers. The failure of adrenalin to help in some cases does therefore in no way speak against its possible usefulness in some other cases. On the other hand, the recovery of some cases does not speak definitely for the usefulness of adrenalin, since 75 per cent. of the patients recover without this treatment. This criticism is applicable to any kind of useful remedy in a disease in which the mortality is comparatively low. However, there is one form of evidence which is of actual value, and that is when an improvement is observed which has to be ascribed to the remedy. That kind of evidence we have unmistakably seen in the experimental poliomyelitis of monkeys, and I may say now that similar evidence has already been obtained in the treatment of human beings. One competent physician wrote to me July 12 the following: "So far have made observations on three cases, on the effect of intraspinal injection of adrenalin. In one case, in particular, the results certainly were good and resembled those obtained by Clark experimentally." Dr. J. C. Regan, resident physician of the Kingston Avenue Hospital, stated to me expressly that he is sure that the intraspinal injection of adrenalin and the administration of oxygen under pressure exert a good effect. In one case, complicated with pneumonia, recovery took place under this treatment. The immediate effect of the oxygen administration upon the cyanosis was unmistakable, and he wished me to let them keep both apparatuses for the administration of oxygen for some time until they could obtain their own. Under these circumstances I am of the opinion that the treatment of poliomyelitis by the measures I suggested is not only permissible but it would be nearly bordering on criminal neglect not to use them. This last statement is perhaps exaggerated, but at any rate, it was my perfect right and duty to bring forward my therapeutic suggestions.

I would like to take issue with several statements of Dr. Emerson; *i.e.* if he was correctly quoted. He stated that the treatment of the sick children is not one of the duties of the administrative part of the Health Department. It seems to me that this position is entirely untenable. If the Health Department has a right to compel people to give up the sick children to its care, it is a positive duty of that department to look out for the proper treatment of these children and to try any method of treatment which promises to do some good. Furthermore, the holding out of hopes of a cure for the sick babies would make the task of the Board of Health in taking the children away from their homes a good deal easier. The department therefore should not discourage such hopes. Finally, if all the children, sick with infantile paralysis are to be treated exclusively in the hospitals under the jurisdiction of the Health Department it is the duty of these hospitals to study new methods of treatment, if any are offered, and are sound; otherwise there would be no therapeutic progress possible for the disease of infantile paralysis. Dr. Emerson is further quoted as saying that adrenalin is not a specific, and therefore does not come within the province of the Board of Health, and he defines a specific as that which offers a cure in every instance. It seems to me that both statements are unsupportable. The antidiphtheritic, antitetanic, and antimeningitic sera surely do not cure in every case. They are, nevertheless, unquestionably specific methods of treatment. On the other hand, it is undoubtedly the duty of the hospitals under the jurisdiction of the Board of Health to apply any reliable method of treatment to the patients entrusted to their care, whether the methods of treatment are specific or not.

The views ascribed to Dr. Emerson, who is probably the best informed medical man who in recent years has presided over the Health Department, are so obviously wrong that I am convinced that he was incorrectly quoted. I discuss these points here merely to impress upon those in power that it is their duty to treat the patients entrusted to them by any available method, specific or non-specific; to study diligently new methods of treatment which are certain not to do any harm and offer some prospect for doing some good, and to manifest to the public rather a hopeful attitude toward the success of any form of treatment.

S. J. Meltzer, M.D.

New York.

A SUGGESTION IN POLIOMYELITIS.

To the Editor of the Medical Record:

Sir:—As the remedy for the prevention or cure of poliomyelitis must be found in the use of a serum, can there be a valid objection to the use of high-grade antidiphtheritic serum as a curative agent during the initial stage of this affection, and is there a valid objection to the use of high-grade antidiphtheritic serum as a preventive agent for adults and children living in close relations with the one afflicted? This serum prevents the onset of paralysis in diphtheria. It modifies the course of scarlet fever.

Furthermore, to prevent the spread of this disease thorough disinfection of each and every house in which it occurs should be enforced, preferably with chlorine gas, as was done in the cholera epidemic of the last century. This disinfection should be undertaken immediately after removal of the patient and when the house is completely empty.

The above serum is as near a cure as we have, and disinfection should prevent the spread of the disease. The term infantile paralysis should not be used, unless there be paralysis, the proper term for this disease being poliomyelitis.

Justin Herold, M.D.

2595 Grand Avenue, Bronx.

THE RIGID OR THE ELASTIC TOURNIQUET?

To the Editor of the Medical Record:

Sir:—These remarks are inspired by an editorial in the Medical Record, July 1, 1916. If the reader will refer to that, brevity is possible here, for that editorial contains timely and practical lessons on tourniquets and on points concerning them that are often misinterpreted or ignored.

Some years ago, at an editor's request, the present writer wrote upon the text "Hemorrhage and a

Wire." At present he cannot recall where it was published. At any rate, the late Dr. Dawbarn shortly before his death came across that article which happened to be printed a few pages removed from something of his own, and of which he was in search. He telephoned at once in about the following words: "Why on earth did you not put that in the RECORD or somewhere where it could be seen. Why! Everybody is fussing and mussing with elastic tourniquets. I have wasted years in experimentation and you here, in this article, make clear that we have only been taking steps to make gangrene and slough; and you show that the force for evil is the follow-through and bruise of elasticity, but what is required is the non-cumulative and set pressure of rigidity." He came to my office, and partially disrobed, and at his request I shut up various arteries. This aroused both his commendation and enthusiasm. He planned to do great things with "Stewart's Wire Tourniquet." He experimented on dogs, horses, and people, and was quite provoked at me because the matter was so absurdly simple in my opinion. His comment was: "That is just it, you think it is of small value because a man may carry the *makin's* of it in his pocket, or like a wrist watch; but to me, therein lies its great value."

The ordinary bloodless method is a series of bruisings, from the firm application of the rubber bandage to the strangulation by the encircling rubber tubing. Pressure from a rigid source will not result in the same amount of damage as that from an elastic one, a rigid ligature will not cut out as rapidly or as completely as will an elastic one; because the rigid loop surrounds a mass of *living* plastic matter which it does not kill by contractility and by an ever-shrinking circumference.

One great handicap to any tourniquet is the dawdling habit which often possesses its manipulator, for slow application insures well-filled veins, therefore an aftercoming operation is very bloody indeed. Speed is a valuable factor in obtaining the best results from a tourniquet.

The manipulation of the wire tourniquet may be varied to suit almost any circumstances. Suppose an arm and an emergency amputation were in question; then elevation of the limb for three minutes, omission of bandages, non-disturbance of germs, mud, etc., and leaving out the usual stripping process will empty the veins, will slow down the arterial current and will do no damage. Gravitation will traumatize but it takes years to spread a vein. While the arm is held in its elevated position a dozen turns of a three-inch gauze bandage (twelve yards long) should be made around and around and exactly superimposed.

To stop the bleeding from a main artery at its branches, put the hard roll of such a bandage upon the gauze turns which it has furnished, press it down directly upon the artery and wire it firmly into place. To influence main, collateral and anastomotic circulation, cut off the roll and make a sort of wire collar over the bandage. Ordinary covered or insulated electric lighting wire is good for such a purpose, but a pair of handles is indispensable for obtaining sufficient traction and its resultant constriction.

The principle involved is that of wiring a garden hose, the tool for that purpose might be employed, but it is too powerful and in undiscerning hands could become almost like a Jarvis snare in effect. I use the handles of a Gigli saw, but Dr. Dawbarn used a couple that he fashioned out of a broomstick, and I am informed that in his research work on surgery of the arteries he could take either one of the two old horses on his farm and open and sew up almost any artery that he chose. Certainly any that would come under the control of a tourniquet. He told me that he never had any slough or gangrene; and jokingly gave as the reason—"The horses are hired for $5 a year, for experimental purposes during my vacation, at the end of which they are returned to their owner. If I should kill them or harm them materially then I am to buy them, or it, at full value."

Three tight encircling wires should be placed, and this is a minimum. Whether spaced an inch apart and holding a roll of bandage against an arterial trunk, or whether a whole limb is to be made bloodless, or whether a perfect collar of wires spaced a quarter of an inch apart, are questions to be settled by the surgeon's judgment. It is important that they be placed upon an empty, elevated, blood-drained by gravity limb, that the distal turn should be applied both first and speedily, and that the skin of the limb should be properly protected by folds or turns of bandage or by a thick folded towel.

Upon such a protection make a loop of wire and give it the first turn of a reef knot. Pull this as tight as you deem necessary, give a couple of twists to your hands and your constrictor is firmly placed. A collar may be made by fastening the first turn, carrying the wire round and round, bandage-fashion, and twisting the ends together securely at the finish. Separate wires spaced (1_2 inch) apart are best, and may be released by severing with wire cutter, with bandage scissors or by twisting with pliers. Wire is too cheap to call for the exercise of any economy, it takes up but little room in pocket or satchel, is not perishable as rubber is, and may be made to serve different purposes, such as cording the extremities or wiring splints. It is hardly fair to patient or method to try any manipulation for the first time in an operating room. And there have been men who could not tighten the wires at all on a first attempt. But a quarter or a half hour spent with one's own leg or thigh as clinical material will smooth out any difficulty for those who are not accustomed to handling wire.

When using pieces of wood or any make-shift handles, the wire must be carefully fastened in order to produce an efficient pull. The Gigli handles may be used as cleats are, and a few turns of the wire about them suffices.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

ALEXANDRA DAY—ROSE FESTIVAL—VICTORIA CROSS FOR CONSPICUOUS BRAVERY; SINTON, SINGH—SICK AND WOUNDED ABROAD—METROPOLITAN HOSPITAL—SIR JAMES GOODHART'S DEATH.

LONDON, June 24, 1916.

WEDNESDAY last was "Alexandra Day," and happily the weather permitted the festival to be successful. It is also called "Rose Day" and is celebrated by almost everyone wearing a little artificial rose on coat or dress front. When London takes up some such movement it is usually done with enthusiasm. This year 15,000 "rose girls" took up their positions at the corners of streets and other likely places as sellers of the flower, and you could buy at any price from a penny to a pound or as much more as you were disposed to contribute. Thirty millions of the little emblems were ordered to meet the demand

in London and other cities. The chief depot in the city was the Mansion House, where the Lady Mayoress superintended 200 vendors. No little amount of trouble is required to command success by enlisting sellers, examining their qualifications and arranging the part to be undertaken by each. But there is always a supply of ardent workers ready to carry out any branch of the service. The money raised goes partly to the hospitals in which Queen Alexandra is particularly interested and partly to homes for cripples. Two of the latter are practically supported by these institutions in which the little cripples are occupied all the year round in making the flowers. They delight in the work. Some who have lost a hand or their lower limbs can do this work and are wheeled or carried into the factory, as may be necessary, and rejoice to meet others engaged in the same way. The oversea dominions join in the celebration. Queen Alexandra takes great interest in the occasion and this time drove round London in an open carriage into which showers of flowers were continually thrown by the loyal crowds.

The King has been pleased to award the Victoria Cross to Capt. John Alexander Sinton, M. B., I. M. G., for "most conspicuous bravery and devotion to duty." Although shot through both arms and through the side, he refused to go to the hospital and remained as long as daylight lasted, attending to his duties under heavy fire. In three previous actions Captain Sinton displayed the utmost bravery.

His Majesty also conferred the Cross on Sepoy Chatta Singh, Ninth Bhopol Infantry, in the Indian Army, for his most conspicuous bravery and devotion to duty in leaving cover to assist his commanding officer, who was lying wounded and helpless in the open, where Singh bound up the officer's wound and then dug a cover for him with his entrenching tool, being exposed all the time to very heavy rifle fire. He remained until nightfall—five hours—beside the wounded officer, shielding him with his own body on the exposed side; then, under cover of darkness, he went back for assistance and brought the officer into safety.

Owing to foreign requirements the relatives of sick and wounded officers cannot visit France except under conditions which the Army Council feels compelled to impose. A telegram granting permission to visit an officer in a dangerous state can be obtained from the War Office when no military or medical objection is present.

At Cambridge the Senate has been discussing the question of throwing open the 1st and 2d M. B. examinations to women. The usual procedure of publishing a report and recommendations and discussing them before taking a vote has not been followed; a vigorous protest signed by the heads of several colleges has been issued. There has been no discussion of the recommendations. The Senate is asked to vote without information, without debate on this controversial question which involves complex problems with serious issues. It seems an undesirable time to bring forward such proposals, for many members of the Senate are away on national service. It is objected by some that instead of invitation to discuss the matter, they have been presented with recommendations without any reports to justify them, but simply told that they have been approved by the General Board of Studies and of the Local Examinations Syndicate. But the Senate has no power of delegating its authority to these bodies. A more natural procedure would be for the special Board for Medicine to present a report for discussion in the Senate, and for any proposals or amendments to be further considered by the Council.

At the annual meeting of the Metropolitan Hospital it was reported that the in-patient accommodation had been increased to three times its size in order to meet the demands for wounded and sick sailors and soldiers. Of the 300 beds, 260 are for military patients. This includes the Howard de Walden wards, which are provided at a cost of £2000 by Lord and Lady Howard de Walden. The year had been a trying one financially, and closed with a deficit of some £3000.

Sir James F. Goodhart died on the 28th ult., aged 70. He was consulting physician to Guy's Hospital, in connection with which one will remember his life's service. He was on the committee of King Edward VII Sanatorium, a Fellow of the Royal College of Physicians, of the Royal Society of Medicine and other societies. In 1898 he filled the presidency of the Harveian Society. His "Common Neuroses" was perhaps his most successful work, but his "Diseases of Children" was equally popular. He was created a baronet in 1911 and is succeeded in title by his son Ernest, honorable secretary to Princess Mary's Sailors and Soldiers' Fund.

6. The Treatment of Paresis by Intraventricular Injections of Diarsenolized Serum. Philip Coombs Knapp.

2. The Menace of Syphilis of To-day to the Family of To-morrow.—J. Harper Blaisdell has tabulated 30 families according to their medical and social histories as they appeared for treatment at the Skin Department of the Boston Dispensary. Of the husbands in this series less than 10 per cent. escaped the infection. Four died with syphilis a contributing factor. Two suffered with insanity. Twelve out of a possible 25 are not taking any treatment. Of the wives 28 out of 30 were infected, and the remaining two probably had the disease. The women were usually the first members of the family groups to come to the clinic and the number under treatment is relatively large when compared with the number of men. There were 132 definite pregnancies in these 30 families. These resulted in only 23 healthy children, the large majority of whom were born before infection entered the family. Of the 53 living children syphilis claims at least 24, or 45 per cent. In the cases of the 79 deaths syphilis may be credited as the probable cause in at least 59 or 74 per cent. The writer also tabulates the age and marital status at the time of entrance to the clinic of 500 consecutive cases of adult syphilis. Of these 500 cases 236 were single men. Two hundred and twelve had early or secondary syphilis and 172 contracted the disease before their thirtieth year. There were only 35 single women who came for treatment during the same period. Yet the 236 men probably represent as many women who are active foci. The bringing under medical supervision of the relatively large number of single women, now apparently under no control, would go a long way toward removing active foci of infection and minimizing the danger to their future husbands and children. A study of the series of single men and women who were syphilitic shows that syphilis is usually acquired by the unmarried of both sexes in early adult life. In closing the essayist states

that the menace of syphilis in the home is one of the greatest problems of preventive medicine and that the early syphilis of to-day can well be depended upon to furnish the family syphilis of to-morrow.

4. The General Practitioner's "Apologia pro Vita Sua."—Andrew F. Downing writes of the lack of unity among the members of the medical profession and of the excess of organization which threatens to become pathological. Division into specialties and subdivision into the branches of the specialties have resulted in a chaotic mass of antagonistic smaller bodies that seem to have nothing in common but contempt for the man in the ranks. The general practitioner rightfully feels that any successful and honest attempt to uplift the rank and file must be accompanied and even preceded by a similar movement to rid the field of specialism of its many mushroom growths. The solution of the problem does not consist in giving to the public the untruthful impression that the general practitioner represents only mediocrity or inefficiency and that the magic word "specialist" always connotes education, training, experience, competency, skill, culture, and intellectuality. The essayist believes that if group medicine is to be what it now pretends to be—better medical service and not medical panhandling—it is an important instrument for the welfare of the people and its success will be linked in a large part with the efficient supervision maintained over it by wise and impartial medical leaders. The general man's idea of efficient group medicine is consultation with—what now seems to be considered an old-fashioned institution—the learned internist. For him it is the original, most serviceable, true and tried method of seeking light in dark places. The good internist is worth a dozen groups and more. The misfortune is that there is not enough of him. Never was he so much needed as he is to-day to deliver some of our specialists and surgeons of pride and covetousness and envy and to encourage the general practitioner to stifle his bitterness and keep "his heart still pregnant with celestial fire." What the general man then demands is that surgeon and specialist be held up to a high standard of efficiency, a standard at least half as high as they would demand of him.

6. The Treatment of Paresis by Intraventricular Injections of Diarsenolized Serum.—Philip Coombs Knapp says that a fairly large experience with the treatment of syphilitic affections of the central nervous system by intraspinal injections of salvarsanized serum by the Swift-Ellis method and its modifications has shown him that in no other way can he so constantly obtain good results. This opinion is reached from the study of about 500 injections on over a hundred patients. His experience, like that of most observers, has led him to accept the hypothesis that the action of salvarsan and its substitutes, neosalvarsan and diarsenol, is most pronounced when it is exerted most directly upon the spirochætes. He has seen tabetics, who could stand only by the support of two nurses when treatment was first begun, who after a few injections would walk several miles with an approximately normal gait. He has seen patients completely paraplegic, with total loss of control over the bladder, leave the hospital walking normally, with complete control over the bladder, and with normal sensibility and reflexes, after three injections. Such brilliant results, however, he had not seen in cerebral cases. He considers the operative procedure fairly safe and feels encouraged to continue with this method.

6. Syncope Immediately After the Administration of Diarsenol. Sylvan H. Likes and Herbert Schoenrich.
7. Chronic Interstitial Nephritis. Francis E. Park.
8. A Trustworthy Nonpoisonous Antiseptic. William M. Gregory.

1. Exophthalmic Goitre.—W. H. B. Aikins reports five cases which serve as examples of the benefit to be derived from the use of radium rays in exophthalmic goitre. He states that his clinical experience shows that, when applied over the thyroid, the more penetrating radium rays diminish the vascularity and reduce the secretion of the gland. It possesses two definite advantages as compared with the *x*-rays; these are, the possibility of giving definite doses, and the fact that it can be applied without noise or excitement, while the patient remains in bed. In view of the fact that injury to the nervous system is an important factor in the etiology of exophthalmic goitre, and as a rule symptoms referable to it predominate in the clinical picture, it follows that one of the essential objects in treatment is to endeavor to relieve these nervous symptoms and that therefore psycotherapy plays an important rôle and consequently physicians who have not had much experience in treating neurotic and neurasthenic people should refrain from undertaking the medical treatment of cases of this kind.

2. Vaginal Hysterectomy.—Joseph C. Taylor says that vaginal hysterectomy is efficient in intraligamentous and retroperitoneal growth, for small fibroids situated near the endometrium in women who have passed the menopause, in complete prolapse after the menopause, in cancer of the cervix where the disease is so far advanced that a Wertheim is likely to result in a cure and is deemed desirable for the relief of pain and the nauseous discharges, and in cancer of the fundus which can be treated equally as well by the vaginal as by the abdominal method. The writer describes his technique of performing hysterectomy based on the technic of division of the uterus into two parts and clamping progressively from above downward. This operation has the advantage that there is never any fear of vaginal hernia owing to the fact that the base of the broad ligament becomes agglutinated to the vault of the vagina and serves as traction to keep the vagina of normal length. The writer has measured the vaginæ of many women before this operation and two years after has found the length to be the same. Painful scars in the vault of the vagina are out of the question inasmuch as the main nerve supply of these parts is cut off during the excision of the cervix. The method described serves in all ordinary cases, but in cases of multiple fibroids the technic has to be modified, and also in cases of complete prolapse. In a series of over 300 vaginal hysterectomies the writer has had but three deaths and none of these could be traced to the operation itself.

6. Syncope Immediately after the Administration of Diarsenol.—Sylvan H. Likes and Herbert Schoenrich state that they have had occasion during the last three months to administer numerous intravenous injections of a preparation made in Canada which the manufacturers claim is identical with the German salvarsan and to which they have given the name diarsenol. They find that the powder seems to dissolve less readily than salvarsan, requires a greater degree of heat for its solution, and gives off a rather strong, garlicky, disagreeable odor. The precipitate which forms after the addition of the alkali is darker, which is also at times the case with the solution when ready for administration. The therapeutic efficacy of the drug does not differ materially from that of salvarsan. On the whole the reaction did not seem to differ very materially from that of salvarsan, although it was observed in a greater percent-

age of cases, and when present came on earlier, was more severe in character, and in three cases it was alarming. In these cases, after the administration of 0.6 diarsenol, the patients went into profound syncope, with profuse sweating and extreme pallor; the wrist pulse was not palpable and in two of the cases there was nausea and vomiting. The writers are of the opinion that these reactions were due to some variation in the form of the drug.

8. **A Trustworthy Nonpoisonous Antiseptic.**—William M. Gregory thinks that the failure of modern antiseptic treatment to meet the exigencies of military surgery in Europe makes it worth while to remind the entire medical profession that they have in calendula a drug that will kill all pus germs. General knowledge of the power of calendula as a germicide and its general use in hospitals and in surgery, would prevent thousands of cases of suppuration and infection every year. This remedy has stood the test of years and is absolutely sure death to all pus germs, but it must be the right calendula. There is much on the market that is almost worthless. The reliable fluid extract is so concentrated that it is almost of the consistence of syrup. In erysipelas, calendula, lead acetate, and a saturated solution of boric acid will be found affective. In leucorrhea, non-alcoholic calendula, non-alcoholic hydrastis, and glycerin are exceedingly efficient. Burns dressed with calendula and saturated solution of boric acid will remain perfectly clean and sterile till healing is complete.

1. Standards for Determining the Suitability of Patients for Admission to a Free Dispensary.—Borden S. Veeder, as a member of a committee appointed to investigate and establish standards for the admission of patients to the new Dispensary of the Washington University in St. Louis, has communicated with a large number of clinics in this country to obtain their standards of admission. This inquiry has shown that a definite standard of financial suitability for admission to free dispensaries has not been based on a study of economic principles involved. There are two more or less distinct purposes for which dispensaries have been established, namely, for purposes of medical education and as a means of furnishing free treatment to the indigent poor. Although it is natural to consider whether the same standard of admission is suitable for each type of dispensary, no such difference has been used in working out the standard prescribed in this paper. A basic income has been worked out for various types of families and individuals below which patients should receive free medical services, and a classified scale of family, consisting of father, mother at home and three children under fifteen years of age, the annual income of which is less than $800 a year, is considered as suitable for free medical treatment. Men or women living independently but with family aid to fall back on are included in the family group. Men, living independently, at labor in which there is steady employment, are entitled to free treatment with a weekly wage rate below $9.50 per week. Women under similar conditions are entitled to free treatment with a weekly wage rate below $8.75 a week. Men living independently, at work in an industry in which there is much unemployment, are entitled to free treatment with a weekly wage below $11, and women under similar conditions if the weekly wage rate is below $10. The writer finds that the problem of dispensary abuse is in reality not so big as it is generally considered. Investigation shows that the actual percentage of abuse, where an effort is made to eliminate it, is small, being at the Washington University Dispensary but 2 per cent. of the patients treated. The various means so far suggested to eliminate this 2 per cent. are impractical.

2. A Critical Analysis of Outpatient Work from the Point of View of Efficiency.—Lovell Langstroth has made a statistical study of 348 records from the Dispensary of the University of California Medical School in the hope that a consideration of the end results of the various examinations and diagnostic procedures might make for greater efficiency in the outpatient department. An examination of the figures makes it obvious that the number of cases is too small to determine the value of the different laboratory procedures. Among the facts brought out are that 38 per cent. of the patients failed to return after diagnosis; 11 per cent. of the patients did not return a sufficient number of times to justify making a diagnosis; in 7 per cent. of the cases it was impossible to make a definite diagnosis; 75 per cent. of the patients sent to the hospital for further examination or treatment had a correct admission diagnosis. Only 38 per cent. of the patients in this series were benefited by their visits to the clinics. Eighty-three per cent. of the patients did not return to the clinics after three months. This study emphasizes the need for the same careful attention to detail and effectiveness in dispensary work that is given to hosiptal work, which it appears is rarely given. The figures show that this work, when considered from the standpoint of end results, is disappointing.

3. Immunity Conferred by the Transfer of Immune and of Mixed Immune and Sensitized Serums.—Henry Sewall, W. C. Mitchell and Cuthbert Powell. (See MEDICAL RECORD, June 17, 1916, page 1111.)

4. Simple Tic Mechanism.—C. P. Oberndorf reports three cases of habit spasm which serve to show that the tic is essentially a defense reaction elaborated by the censor against a primarily autopleasurable act. It constitutes when regarded as an entity, a compromise, just as most other neurotic symptoms are compromises, to retain and at the same time abandon an act which originally yielded satisfaction but which has become intolerable because it cannot be brought to harmonize with the individual's idea of adult or adolescent propriety. The mechanism in the tics reported are all very simple, and all disappeared, not because of their analysis, but because more vexing problems harassing the patients were solved and the necessity for such supplementary compromise defense reactions no longer existed. The cases thus illustrate the theory that these tics originally represented purposes, that the purpose had been suppressed, and how the apparently senseless movement, when resumed, constituted a simple defense compromise which afforded relief to the patient.

7. Condyloma Acuminatum of the Anal Region in the Male.—A. Ravogli comments on the rarity of the occurrence of condyloma acuminatum in the anal region of the male and reports two cases which have come under his observation in his hospital service. In both of these cases it can be said that the condyloma has had its origin on the skin and mucous membrane injured

by syphilis and that the constant presence of normal and abnormal secretions and lack of cleanliness have caused the proliferating acanthosis. The syphilitic base is only accidental, however, and not necessary for the production of the condyloma. On a mucous membrane or on the delicate skin of the genitals, excoriated from the irritating secretion of the gonorrhea, or an excoriated surface left so by the presence of chancroids, papillary hpertrophy may develop with the formation of condylomatous growths. In the cases in which the acanthosis has a syphilitic base, the growths are produced on a base hard and infiltrated, and in this case very likely the presence of the spirochete is capable of causing vegetation. When the syphilitic infiltration has been removed through local antisyphilitic treatment, the proliferations also gradually disappear. In the case of cyndylomata, on the contrary, no application stops the growth of the tumors and the treatment rests entirely on the destruction and removal of the papillary growths. The writer uses the sharp dermal curette to scrape the growth from its roots, and then touches the bleeding wound with ferric chloride. In the two cases reported the whole mass was removed with most satisfactory results.

9. Angina Epiglottidea Anterior. Report of a Case Caused by the Bacillus Influenzæ.—Sam N. Key says that in spite of the conflicting evidence on the question of whether angina epiglottidea anterior is a separate pathological process, or only a part of a general involvement of the adjacent structures, it is an undeniable fact that a curious inflammation of the epiglottis in which there is remarkably little involvement of the rest of the throat does occur. In the case reported the ulceration and edema of the anterior surface of the epiglottis was caused by the *Bacillus influenzæ*. It occurred during an epidemic of grip in the patient's community. In his case all the evidence of active inflammation was confined to the epiglottis, the process seemingly being primarily in the epiglottis. It is suggested that the *B. influenzæ* may, under certain conditions, have a selective activity for the epiglottis and that it is possible that this may be of more frequent occurrence than has been supposed.

6. The Diagnosis of Dextrosuria and Pseudo-Lævulosuria. P. J. Cammidge.

2. A Contribution to the Etiology of Shell Shock.—Harold Wiltshire states that the functional nervous affections of modern warfare are essentially the same as the functional nervous affections of civil life, and in consequence should be of great value in helping to elucidate problems connected with the etiology of the functional nervous diseases in general. He points out that at the present time the etiology of shell shock is buried in confusion owing to three main difficulties, namely, bad terminology, dubious clinical histories, and rapid changes in clinical condition. In view of this confusion he discusses the possible etiological factors under the following headings: 1. Wounds. 2. Possible physical causes. 3. Possible chemical causes. 4. Possible psychic causes. 5. Causes of relapse. His practical experience with this class of cases leads to the following conclusions: 1. The wounded are practically immune from shell shock, presumably because a wound neutralizes the action of the psychic causes of shell shock. 2. Exposure and hardship do not predispose to shell shock in troops who are well fed. 3. While it is theoretically possible that physical concussion resulting from a shell explosion might cause shell shock, it is certain that this must be regarded as an extremely rare and unusual cause. 4. Chemical intoxication by gases generated in shell explosions cannot be more than a very exceptional cause of shell shock. 5. Gradual psychic exhaustion from continued fear is an important disposing cause of shell shock, particularly in men of neuropathic predisposition. In such subjects it may suffice to cause shell shock *per se*. 6. In the vast majority of cases of shell shock the exciting cause is some special psychic shock. Horrible sights are the most frequent and potent factor in the production of this shock. Losses and the fright of being buried are also important in this respect. Sounds are comparatively unimportant. 7. A consideration of the causes and frequency of relapses favors an original cause of psychic nature. 8. Any psychic shock or strain may cause a functional neurosis, provided it be of sufficient intensity relative to the nerve resistance of the individual. Such shock or strain need not have any connection with "sex complexes."

3. Failure of the Right Side of the Heart as a Result of Extensive Pulmonary Disease.—F. J. Poynton cites two cases, one of chronic pulmonary tuberculosis and a second of extensive pulmonary sclerosis and bronchiolectases, in which the pulmonary condition had fallen into the background and a series of symptoms, apparently cardiac, had become predominant. Dyspnea had increased; a very striking lividity of the whole integument, and notably of the face and extremities, had become permanent; dropsy and ascites had attained a high grade, and the liver in both cases was greatly enlarged. Venous engorgement was conspicuous, but the pulses—a point of importance—though strikingly rapid (120 to 140 per minute) were not arrhythmic; and the quantity of urine passed was considerable. These, together with the tricuspid systolic mumur, were the features which attracted attention and made it clear that some very definite change had taken place in the course of these illnesses. Radiographic examination showed that the enlargement of the heart was symmetrical owing to the disproportionate size of the right side. The outline is not so circular, as in failure the result of mitral disease and the transverse measurement is not so great. The left border of the outline is not so circular as in mitral disease with failure of compensation, but makes an obtuse angle, the apex of which is formed by the junction of the upper limb constituted by the left ventricle with the lower formed by the right ventricle. The writer thinks these facts should be borne in mind in connection with the progress in thoracic surgery in recent years, especially the possibility in performing artificial pneumothorax that, in putting out of action a considerable portion of functioning lung which disturbs the balance of pulmonary circulation and throws considerable strain on the right ventricle, the reserve power in weakly subjects may be rudely shaken and secondary heart failure encouraged.

4. The Effect of Ferrivine and Intramine on Syphilis.—L. W. Harrison and C. H. Mills have tested the action of ferrivine and intramine in three cases of syphilis and have found that these agents have entirely failed to cause the *S. pallida* to disappear from the lesions of three well marked cases of secondary syphilis. After the failure of ferrivine to cause the diappearance of *Spirochæta pallida* from a mucous patch a single dose of salvarsan effected this in 18 hours. Clinically they

were unable to detect any influence of either or both of these compounds on syphilitic lesions, although each of them was of the variety which heals in a week or ten days under salvarsan treatment. These investigators also find that intramine and ferrivine are extremely unpleasant in their effects. They have no specific effect on early syphilis.

6. **The Diagnosis of Dextrosuria and Pseudo-Lævulosuria.**—P. J. Cammidge emphasizes the clinical importance of distinguishing between these two conditions. He finds Benedict's test for sugar in the urine more sensitive and reliable than the test with Fehling's solution. With 0.3 per cent or over, of dextrose it gives a characteristic reaction on boiling, but with smaller quantities the precipitate forms only on cooling. A similar delayed reaction is characteristic of pseudo-lævulose (iso-glucuronic acid), which does not reduce alkaline copper solutions as readily as dextrose. The formation of a precipitate as the solution cools is suggestive, therefore, of pseudo-lævulose or a small quantity of dextrose. To differentiate the two, Borchardt's modification of Seliwanow's test is employed. A mixture of 4 cc. of the urine and 1 cc. of Seliwanow's reagent (resorcin, 0.5 gm.; hydrochloric acid, sp. gr. 1.195, 30 c.c.; distilled water 30 c.c.) is heated to boiling in a water bath for a few minutes. If pseudo-lævulose or true lævulose is present the solution assumes a purple-red color, but dextrose alone gives no color change. To differentiate pseudo-lævulose from true lævulose the solution is cooled, made alkaline with solid sodium carbonate, and extracted with 2 or 3 c.c. of ethyl acetate. If true lævulose is present the ethyl acetate extract is red or pink, but if the positive result was due to pseudo-lævulose the watery solution retains the pigment, and the extract is yellow or brown. The diagnosis may be confirmed by preparing the para-bromphenylosazone and taking its melting-point. The osazone of pseudo-lævulose melts at 256° C., that of true lævulose at 197° C., and the osazone of dextrose at 220° C., while the hydrazone of glycuronic acid melts at 236° C.

1. **The Fasting Treatment of Diabetes.**—E. I. Spriggs relates his experience with the fasting treatment of diabetes which he used before he became acquanted with Dr. Allen's work. He reports five typical cases and outlines his procedure which consists in a two days' fast, allowing nothing but a cup of weak tea with 10 cm. of 20 per cent. cream at breakfast and tea-time. After the first two days 150 cm. of clear meat broth is added at lunch and dinner time. If acidosis is present after two days of fasting, alcohol may be allowed, 0.12 gram per kilogram of body weight being given in the form of whiskey four times a day. In the cases reported no alcohol was used. When the urine has been sugar-free for twenty-four hours, 7.5 grams of carbohydrate is added in the form of vegetables which contain low percentage of carbohydrate. On the second day of feeding 30 cc. of cream is allowed with each cup of tea, and three eggs are added. On the third day a feeding, and on each alternate days subsequently, 5 grams of carbohydrate is added. Vegetables containing higher and higher percentages of carbohydrate are used, and finally porridge, oatcake, macaroni, bread, and fruit. The addition of carbohydrate is continued until sugar appears or the tolerance reaches 3 grams of carbohydrate per kilogram. At the same time 15 grams of protein in the form of meat and fish are added daily up to one gram per kilogram, or, in certain cases, more. When the protein has reached the desired amount, fat is added until the patient stops losing weight or is getting 40 calories per kilogram. If sugar at any time recurs in the urine the patient is again fasted until the urine is sugar-free for twenty-four hours. The diet is then resumed at the point where it was left off, but on only one-half the amount of carbohydrate is given until the urine has been sugar-free for two weeks. In summing up his observations the writer says that fasting up to several days is well borne by cases of mild and severe diabetes of ages ranging from 24 to 79 years. The urine was made free from sugar, the blood sugar was reduced, and acidosis greatly diminished. In most cases the food could be increased gradually without glycosuria. The rapid abolition of sugar had an excellent effect on the patients. It shortened tedious treatment, and enabled more time to be given to finding out what food should be taken and in what quantity. For the majority of diabetic patients Dr. Allen's treatment offers great advantages. There is evidence enough that such patients, though not cured, may be freed from the signs and symptoms of their complaint.

2. **A Simple System of Skeleton Splinting.**—C. Max Page calls attention to the value of skeleton splinting in the treatment of gunshot fractures and describes a system which he finds superior to the aluminum stapled strips which he described some time ago. He has found that the aluminum strips are not always sufficiently rigid for prolonged treatment and that, furthermore, the supply of aluminum for surgical purposes is limited. He finds annealed steel the most satisfactory material available. The stock material consists of five foot lengths of annealed mild steel ½ inch by ⅛ inch. The strips are drilled throughout their length at one inch intervals with holes of 1/6-inch diameter. Split steel rivets are required to couple the various lengths after they have been bent to form the splint required. The writer describes in detail the tools required, the method of cutting, bending and coupling the strips, and gives the measurements and details of constructing some of the more commonly used splints. Modifications in size and designs will often be necessary, but can readily be carried out. The splints can always be reinforced if exceptional rigidity is required by the addition of arches or by riveting extra lengths on the main frame.

4. **The Inhibitory Action of Saliva on Growth of the Meningococcus.**—M. H. Gordon describes experiments which have shown that normal saliva and saliva from meningococcus carriers inhibits the growth of the meningococcus upon solid artificial culture medium (nasgar). The nasal mucosa from normal persons has no such inhibitory effect on the growth of meningococcus. A quantitative experiment showed that fresh saliva does not lose this inhibitory influence when diluted a hundred-fold. This antimeningococcal action of saliva is due to its living bacteria. A young broth culture from saliva is at least as efficacious as fresh saliva in antimeningococcal action. This effect is due to the living and multiplying bodies of bacteria in the broth. When they have been separated off by a Berkefeld filter, or killed by heat, the broth has lost its meningococcal power. This inhibitory action of saliva appears to be due chiefly to mixed salivary streptoccoci. Pure cultures of predominant streptococci, when tested individually, were found to exert comparatively slight inhibitory influence on the growth of meningococcus. These observations demonstrate the practical importance of avoiding contamination with saliva when swabbing the nasopharynx of suspected carriers.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Special Meeting, Held July 13, 1916.

THE PRESIDENT, DR. WALTER B. JAMES, IN THE CHAIR.

THIS meeting was held in Aeolian Hall as the Academy of Medicine could not accommodate the large number in attendance. The meeting was called to discuss the subject of Poliomyelitis.

Infantile Paralysis: What We Know About the Transmission of the Disease.—Dr. SIMON FLEXNER presented this communication. He said that infantile paralysis was caused by the invasion of the central nervous system by a minute, filterable microorganism which had now been secured in artificial culture and as such was distinctly visible under the higher powers of the microscope. The virus of infantile paralysis existed constantly in the central nervous organs and upon the mucous membrane of the nose and throat and of the intestines in persons suffering from the disease; it occurred less frequently in other internal organs and had not been detected in the circulating blood of patients. The difficulties attending the artificial cultivation and identification of the microorganism of infantile paralysis were such as to make futile the employment of ordinary bacteriological tests for its detection. Nevertheless the virus could be detected by inoculation tests upon monkeys. The virus had an apparently identical distribution irrespective of the types or severity of cases of infantile paralysis. The virus was known to leave the infected human body in the secretions of the nose, throat, and intestines, and also escaped from contaminated healthy persons in the secretions of the nose and throat. The virus entered the body, as a rule, if not exclusively, by way of the mucous membrane of the nose and throat. It multiplied in these localities and then penetrated to the brain and spinal cord by way of the lymphatic channels which connected the upper nasal membrane with the interior of the skull. As the virus was thrown off from the body mingled with the secretions, it withstood for a long time even the highest summer temperatures, complete drying, and even the action of weak chemicals, such as glycerin and carbolic acid. Hence mere drying of the secretion was no protection; on the contrary as the dried secretions might be converted into dust, which was breathed into the nose and throat, they became a potential source of infection. The survival of the virus in the secretions was favored by weak daylight and darkness and hindered by bright daylight and sunshine. It was readily destroyed by exposure to sunlight. The blood-sucking insects had been suspected of conveying the disease. Certain experiments did indicate that the biting stable fly could both withdraw the virus from the blood of the infected and reconvey it to the blood of healthy monkeys. More recent studies had failed to confirm these earlier ones. Domestic flies experimentally contaminated with the virus remained infective for forty-eight hours or longer. While our present knowledge excluded insects from being active agents in the dissemination of infantile paralysis, they nevertheless fall under suspicion as being mechanical carriers of the virus of that disease. The animals that had especially come under suspicion as possibly distributing the germ of infantile paralysis were poultry, pigs, dogs, and cats. Experiments had, however, excluded these animals from being carriers of the virus of infantile paralysis. Studies carried out in various countries in which infantile paralysis had been epidemic all indicated that, in extending from place to place, the route taken was that of ordinary travel. In other words the evidence derived from this class of studies confirmed the evidence obtained from other sources in connecting the distributing agency intimately with human beings and their activities. The virus of infantile paralysis was destroyed more quickly and completely in the interior of the body than, in some instances, in the mucous membrane of the nose and throat. It had been found in monkeys that the virus might disappear from the brain and spinal cord within a few days to three weeks after the appearance of the paralysis, while at the same time it was present on the mucous membranes mentioned. The longest period after inoculation in which the virus had been detected in the mucous membrane of the nose and throat of monkeys was six months. In an undoubted case of the human disease the virus was detected in the mucous membrane of the throat five months after its acute onset. This was conclusive evidence of the occurrence of occasional chronic human carriers of the virus of infantile paralysis. A study of the virulence of the virus in various epidemics showed that it was subject to great fluctuations of intensity. Not all children and relatively few adults were susceptible to infantile paralysis. Young children were more susceptible, generally speaking, than older ones. The light or abortive cases indicated a greater susceptibility to the disease than had generally been recognized. The period of incubation might be as short as two days or as long as two weeks or more; the usual period, however, did not exceed about eight days. Probably the period at which the danger of communication was greatest was during the very early and acute stage of the disease. (This statement was made tentatively.) Cases of infantile paralysis that had been kept under supervision for a period of six weeks from the onset of the symptoms might be regarded as practically free of danger. One attack of infantile paralysis conferred immunity. Protection had been afforded monkeys against inoculation with effective quantities of the virus of infantile paralysis by previously subjecting them to inoculation with sub-effective quantities of the virus. This method, however, had not been successful in all instances. Passive immunity had been conferred on monkeys, but it was somewhat uncertain and its brief duration rendered it useless for purposes of protective immunization. However, a measure of success had been achieved by the experimental serum treatment of inoculated monkeys. For this purpose blood serum from recovered or protected monkeys or human beings had been injected into the membranes about the spinal cord, and the virus was inoculated into the brain. The injection of the serum must be repeated several times in order to be effective. The results from this treatment were said to be promising. Unfortunately no other animal than the monkey seemed capable of yielding an immune serum, and the monkey was not a practicable animal from which to obtain supplies. Hexamethylenamin was the only drug which had shown any useful degree of activity. Experiments on monkeys had shown this drug to be effective only very early in the course of the disease, and only in parts of the animal treated. From our present knowledge certain practical deductions might be drawn. Since the chief mode of conveyance of the virus was through human beings, either those ill with the disease or healthy carriers, and since the domestic fly might be grossly contaminated with the virus and might deposit it on the nose or mouth of a healthy person, or upon food or eating utensils, our efforts must be directed to the control of these sources of infection. Protection to the public could best be secured through the discovery and isolation of those ill of the diesease, and through the sanitary control of those who had associated with the sick and whose business called them away from home. Parents should consent to the removal of children ill with the disease to a hospital both in the interest of the sick child and in the interest of other children. This removal must include not only frankly paralyzed cases but also other forms of the disease. In concluding, Dr. Flexner said it was too early to calculate the death rate in the present epidemic; it might prove to be considerably lower than it now appeared to be. Of those who survived, a part made complete recoveries and this number was greater than was usually supposed. The knowledge regarding infantile paralysis was now far greater than in 1908 and the forces in the city which were dealing with the epidemic were better organized than ever before. The outlook, therefore, should not be regarded as discouraging.

The Clinical Types of the Disease.—Dr. HENRY KOPLIK read this paper. He said that poliomyelitis was primarily an epidemic disease and as a sporadic condition it had attracted very little notice. All the epidemics which had thus far been recorded resembled each other very closely. An attempt to connect this disease with the occurrence of cerebrospinal meningitis had developed into a belief that poliomyelitis was an entity, clinically occurring in epidemics in the late spring to late autumn and following the regular sporadic occurrence of the disease in limited numbers in the months following the winter and reaching into the late spring up to the time of the epidemic outbreaks. Epidemics of this disease had been known to skip a year and to always crop up again in the place of the original occurrence which should give the thoughtful hint as to the possible cause of its epidemiology. In all the epidemics thus far recorded, the symptomatology and clinical types had been much the same. Though most of the scientific knowl-

edge of the clinical types of poliomyelitis was borrowed from Swedish and Norwegian observers, Medin and Wickman, the first inkling of the epidemic nature of the disease was voiced by Colmer, an American physician, who in 1841 observed some form of paralysis in a child and obtained the history that in the locality in which the patient lived several similar cases had occurred and most of them had recovered. Following him, Caverly in 1894 described the epidemic in Vermont; Taylor and Chapin later on observed the epidemic nature of the disease. Aside from these observers, much of the clinical knowledge at present was due to Medin who described the clinical types of acute epidemic poliomyelitis in 1884 before the International Congress, much to the astonishment of most pediatricians who still retained the simple picture of poliomyelitis anterior as retained in older text books—as a simple infantile paralysis. In all, 42 epidemics had been observed in American and the Continent and this alone should establish the tendency of poliomyelitis to occur in epidemic form at certain seasons and remain sporadic until the time arrived for a new outbreak. This disease selected the young as its victims. Out of 886 cases in the epidemic of 1907, 571 were below 3 years of age, 771 below 5 years, and 3 were under 6 months of age. In the present epidemic the youngest case Dr. Koplik had seen was four and a half months old and absolutely breast-fed. The most susceptible period was from 1 to 3 years of age. There were four principle types which could be clinically described and proven by laboratory methods: (1) the abortive; (2) the bulbospinal; (3) the cerebral and meningeal, and (4) the bulbopontine types. Wickman had described a neuritic type. These types could all be understood when poliomyelitis was regarded from the standpoint of an acute, infectious disease, involving certain parts of the general nervous structures, causing certain definitely marked pictures and there stopping, or going on at one stroke to involve the whole cerebrospinal axis and in this way causing a debacle of the whole substratum of the nervous economy.

2. *The Abortive Type.*—It was through the abortive type of the disease that these cases were spread to others. This type was that which did not go on to paralysis, recovered, and did not leave the host injured so as to leave no doubt as to its distinct identity. A child of 5 years of age was attacked with a headache, slight malaise, and an attack of vomiting lasting five days, intense pain in both lower extremities radiating to the soles of the feet and worse at night, slight pain in the nape of the neck, lassitude, cerebellar gait on walking, increased reflexes in the lower extremities, rectal temperature above 100.5 deg. Fahr. In ten days the pains had disappeared, the child was well and wanted to go out and play. The abortive cases presented prodromata such as headache, weakness, diminished reflexes and pains in the nape of the neck, with or without vomiting and fever, and still did not present paralysis and recovered.

2. *The Bulbospinal Type.*—This was the most common type and gave the disease its name. The patient would have an attack of vomiting and slight fever and within twenty-four hours the mother would observe that the child could not move one or the other extremity. These forms might have no fever, but it was possible in giving the history the mother might have overlooked the symptoms of fever, malaise, and such indisposition as peevishness, which might have preceded by a few days the paralysis. In other cases the paralysis appeared gradually. Pain might continue to be quite severe, especially when the extremities were moved. The paraylsis might spread and involve not only the remaining lower extremity, but the upper extremities, the muscles of the back, the respiratory muscles of the thorax, and possibly the muscles of the abdomen. As a rule, in the purely spinal cases, the paralysis appeared and did not spread in the great number of cases. In others, it might spread from the extremities and involve the whole trunk, even to causing bulbar paralysis of the respiratory centers. But after the tenth day, paralysis was not apt to spread to the bulbar medulla, though cases had been known to die after the fifteenth day.

3. *The Cerebral and Meningeal Types.*—Both the meningitis and cerebral types should be combined because of the cerebral symptoms which gave rise to a picture closely simulating meningitis. The meningitic form of poliomyelitis ran its course with cerebral symptoms. A child of three was taken with vomiting for forty-eight hours, followed by rigidity of the neck with pain on flexion of the head, Brudzinski's sign and reflex, Kernig's sign, sopor, and Macewen's symptom which might be slightly marked; also diminished reflexes. Some patients migh improve after a day or two, the fever might abate and they might even be about and then have a recrudescence of fever, sopor, rigidity, delirium, irritability, extreme hyperesthesia, and pain in the nape of the neck. In some cases the only palsy might be ocular; in others a slight facial palsy might be present which might be combined with a weakness in one or other extremity. After a week the patient became brighter. There was still, however, marked ataxia and Romberg's sign. As convalscence was established, the ataxia was the last symptom to disappear. The hydrocephalus and abnormal mental state might remain for some time after the temperature was normal. On recovery, there was a slight strabismus, ataxia, or optic neuritis. In one group of cases he had seen unilateral ophthalmoplegia with hemorrhages into the retina. In lumbar puncture lay the differentiation of this form of poliomyelitis from cerebrospinal meningitis.

4. *The Bulbopontine Type.*—The bulbar or pontine form of the disease deserved notice as a distinct form. An infant, breast-fed, thirteen months of age, was attacked with fever and vomiting. The fever continued into the afternoon of the following day, when the mother noticed a flatness on the right side of the face. The temperature continued at 102.4°, the infant was bright, laughed, and played in the crib, but there was a tired look about the face and eyes. The knee reflexes were increased; otherwise there was no paralysis that could be demonstrated. In another case, ten days before the patient, aged twenty-one months, was seen, he was taken with high fever and vomiting and there were some green movements. The fever continued, in a less degree, to the ninth day when the mother noticed that the right side of the face was flat; there were tremulous movements of the head and arms and the patient was restless. There was constant jactitation of the head and insomnia; there was rigidity of the neck, but no palsies of the extremities; on the contrary, the patient exhibited great strength in both the upper and lower limbs. In other cases, the outcome was not so favorable; there was an involvement of the nuclei which controlled deglutition and respiration. In these cases the patient might be lost by paralysis of the respiratory centers. The neuritic type included those cases in which pains in the extremities became a leading feature of the clinical picture. Some of these cases developed paralysis; others did not. They were referred to under the head of abortive cases. The symptoms given justify a lumbar puncture in order to establish the character of the fluid which in poliomyelitis showed a lymphocytic cytology and an increase of globulin. The examination of the blood was very uncertain. As to prognosis, the low mortality of 10 per cent. applied to children below eleven years of age, and 27 per cent. among older children and adults. Twenty per cent. of all cases completely recovered and the younger the child the better the prognosis.

Abortive and Nonparalytic Cases, Their Importance and Their Recognition. — Dr. GEORGE DRAPER discussed this phase of the subject. He took exception to the term "abortive." He said this term had been used when attention was centered on the paralysis as the chief symptoms of poliomyelitis. As our knowledge had grown it had became increasingly evident that in acute anterior poliomyelitis we were dealing with a general infection that presented a great variety of manifestations. The cases that escaped paralysis were just as important from the standpoint of the spread of the infection as the paralyzed cases. In fact they were infinitely more dangerous. These cases that were called "abortive" should be called "atypical," if those that developed paralysis were considered as typical. There was no possible way at the present time of determining the number of cases that were not paralyzed. Such figures as had been collected varied greatly and undoubtedly the number of cases that were not paralyzed varied greatly in different epidemics. There were certain indications, however, that led to the belief that the number of these cases was considerable. Investigation had shown that frequently where there had been one case of poliomyelitis in a family another child had shown mild symptoms, as fever, general malaise, and vomiting. Pathological studies had shown that there might be not only lesions in the spinal cord, but that the entire lymphatic apparatus and the viscera might be involved. Palpably enlarged lymph nodes might be

observed. This furnished further evidence that poliomyelitis was a general infectious disease. Cases of infantile paralysis fell into the following groups: (1) Gastrointestinal. (2) Respiratory. (3) Febrile. (4) Meningismic. (5) Paralytic. In the first three types there might be slight transient paralysis. In the type showing paralysis one might find any or all the prodromal symptoms seen in the other types. The intensity of the symptoms was no guide to the prognosis. In fatal cases more extensive lesions of the cord had sometimes been found than were indicated by the symptoms. That there should have been this general degeneration of the cord without clinical manifestations suggested that in the milder cases there might be cord lesions that gave no clinical evidence of their existence. In times of epidemic every one was alive to the symptoms of poliomyelitis, but it was not enough for a physician to say that a given case was or was not one of infantile paralysis. In suspicious cases lumbar puncture should be done, and the spinal fluid examined. There was usually an increase in the lymphocytes and a very large percentage of polymorphonuclears, which changed within twelve hours to mononuclears, and in three or four days there was a leucocytosis. The albumin and globulin content of the fluid were increased but less so than in tuberculosis meningitis. Reduction with Fehling's solution was good. The diagnosis was based on the finding of gastrointestinal respiratory and febrile symptoms. Gastrointestinal symptoms were of course present in many conditions and infections. The respiratory symptoms might resemble those of influenza, such as lung signs and pains in the bones and joints. Where the above-mentioned symptoms were found a search should be made for transient weakness and mild degrees of paralysis and for local muscle tenderness. One point of value in the diagnosis was the anterior spinal flexion sign. Before paralysis set in this sign was definitely present. It could be elicited by having the child place his hands under his thighs and then flexing the trunk forward, doubling the child up. There was no longer any question but that these atypical cases of poliomyelitis existed. They must be recognized and herein lay the problem. In learning to recognize them a double advantage would result. The cases as moving sources of contagion would be controlled and those that were destined to be paralyzed would be recognized in the preparalytic stage and could be treated early when a remedy was discovered, and thus possibly saved from oncoming paralysis.

The Present Epidemic: The Types Which It Presents. Dr. Louis C. Ager spoke more particularly of his personal experience at the Kingston Avenue Hospital. He stated that it would be generally understood that the amount of clinical work that they had had to accomplish during the epidemic had left no time in which to write a paper or to digest the large amount of clinical data that had accumulated. This data would be put in shape for presentation at some future time. When it was recalled that from June 20 to July 12 they had cared for 320 patients with poliomyelitis in the Kingston Avenue Hospital, the fact would be appreciated that the resident staff were brought face to face with a large number of serious problems. He wanted the people of New York to get some idea of what they had accomplished. On July 3 there were eighty-nine patients admitted to the hospital, and on that day the ambulance surgeons had only three hours sleep and no meals. A most striking feature in connection with this work was the great degree of comfort experienced by the patients after they were brought to the hospital from homes unsuited to the care of children sick with an infectious disease. The best feature in the scheme of hospitalization of these cases was the beneficial effect on the children themselves. Dr. Draper had spoken of the large number of abortive cases, and in this class of cases they have had more proof of the infectivity of poliomyelitis than had been evident before the present epidemic began. In this connection such examples as the following might be cited: On July 2 a child was taken ill with convulsions, vomiting, and fever, but recovered. On July 3 another child in the same family was stricken with the acute fulminating type of the disease and died within forty-eight hours. On July 4 an older member of the family developed the disease. At least eight instances had come under their observation at the Kingston Avenue Hospital in which there had been two or more cases in the same family. That there are practically no cases of poliomyelitis among colored people is borne out by our experience at the Kingston Avenue Hospital. Investigations having for their object the detection of a racial susceptibility had not revealed any racial predisposition to the disease. With reference to the affection of the liver and spleen, they had found no material enlargement in these organs except in some fulminating cases. In a series of sixty-seven cases they found only two with enlarged livers. The age incidence was practically the same in the present epidemic as in the epidemic of 1907. The epidemics in this country seem to show a lower age incidence than those abroad. In one group of eighty-seven cases, forty-six occurred between the ages of 2 and 5 years; twenty-two between the ages of 1 and 2 years; eight between the ages of 6 and 12 years; three between 1 and 6 months. They had two adult cases in this group, one in a woman of 28 years of age and one in a pregnant woman of 21 years. They had found as usual that the lower extremities were most frequently paralyzed. In a group of sixty-four cases examined, the lower extremities were involved in thirty-nine instances; the upper in seven; there was facial paralysis in five cases, and in thirteen the only definite symptom was marked paralysis of the muscles of the back. There were two typical ataxic cases. A few special types had been seen. There was one peculiar and unusual case in a boy of 11 years. He was a well-nourished, well-developed child. When brought to the hospital his only symptom was markedly labored breathing. He asked for a drink of milk and it was noticed that there was a slight blur to his speech. When he tried to drink he was unable to do so because of pharyngeal paralysis. His diaphragm was completely paralyzed. He was able to use his arms and hands, could stand up in his crib, and his back showed no evidence of paralysis. He gradually became weaker and died five hours after entering the hospital. Another case of the fulminating type showed a general paralysis; practically all the skeletal muscles were affected and there was marked respiratory paralysis. In neither of these cases was the heart affected. They had tried artificial respiration with Dr. Meltzer's apparatus, and in some instances had succeeded in bringing back the color after death had apparently occurred. They still hoped that in some cases something might be accomplished by this method. They had also observed a meningitic type of the disease. They had had one older boy who was wildly delirious. He had complete paralysis of one leg and one arm, and was totally blind. There was an alternation in his condition from deep meningeal coma to active maniacal delirium. During the epidemic they had received six calls to see croup cases for the purpose of intubating and when they had reached the patients found respiratory paralysis and poliomyelitis. It was sometimes extraordinary to see the rapid improvement that took place in some cases. Some bottle-fed babies who were unable to take their milk at first were now able to hold the bottle and feed themselves. In closing, Dr. Ager emphasized the fact that their experience had absolutely convinced them that the only place in which to take care of children with poliomyelitis was in a hospital, unless the conditions of the hospital could be reproduced in the home.

Laboratory Aids in the Diagnosis of Poliomyelitis.—Dr. Josephine B. Neal said that it was well known that sporadic cases of poliomyelitis were frequently seen when no epidemic existed. Because of this fact, during the past six years it had been the lot of the Miningitis Division of the Department of Health to study, both clinically and by means of laboratory methods, many cases of this disease before the present epidemic occurred. Most of the cases seen by them, both before and during this epidemic, had been atypical, and they had, therefore, been compelled, when endeavoring to make a diagnosis, to consider their laboratory findings with more than ordinary care. As with most such procedures, the answers which the laboratory returned to their questionings furnished them with evidence that was corroborative *only*, and by no means absolutely diagnostic. Perhaps one of the most interesting experiments employed in the study of poliomyelitis had been the inoculation of monkeys by means of washings from the respiratory and alimentary mucous membrane. This was first successfully performed by Kling, Petterson, and Wernstedt in 1911. It had since been repeated several times. Dr. DuBois, Dr. Zingher, and Dr. Neal obtained washings from the nose and throat from an abortive case two weeks after the incidence of the disease. With these washings they produced typical poliomyelitis in monkeys. In sections of the brain from one of these monkeys a few globoid bodies similar to those described by Flexner and Noguchi were found.

Another laboratory method of some diagnostic value was the so-called neutralization test. In this, serum from the suspected case, in the stage of recovery, was mixed with an old fatal dose of an active virus. These were incubated, and later injected intracerebrally into the monkeys. Failure of the disease to develop indicated that the virus had been neutralized. This test, however, did not furnish conclusive evidence of poliomyelitis, for sera from noses known to have been free from a recent attack of the disease had sometimes successfully neutralized the virus. It was, however, quite obvious that laboratory methods requiring the use of monkeys were both too complicated and too expensive for ordinary diagnostic use. A study of the blood picture was exhaustively made by Peabody, Draper, and Dochez of the Rockefeller Institute. It was shown that there existed a varying increase in leucocytes and a polymorphonucleosis. This was characteristic of so many other diseases that it was of little value in diagnosis. The procedure which they found to be their most reliable and valuable aid in the recognition of poliomyelitis was the examination of the spinal fluid. In the first twenty-four to forty-eight hours after its onset, poliomyelitis must be differentiated from the early stages of epidemic meningitis or mild purulent meningitis, and also from a meningism accompanying pneumonia or other infection. The clinical picture presented by these diseases were quite similar, and it was in the distinguishing between them that the examination of the spinal fluid afforded them the most valuable information. In the early stages of poliomyelitis, the spinal fluid was clear, or rarely it might be slightly cloudy. It often showed a good fibrin web formation. There was a slight to moderate increase of albumin and globulin, and also of the cellular elements. The reduction of Fehling was prompt. Those poliomyelitis fluids which were cloudy presented a polymorphonucleosis which might run as high as 90 per cent., but which they usually found to be about 60 per cent. As a rule, however, 80 per cent. or more of the cells were mononuclears. In examining such fluids, they had frequently observed the presence of large mononuclear cells, which they believed to be, in a measure, characteristic of poliomyelitis. They were now studying these by means of the various differential stains, in the hope that their research in this direction might develop something of positive diagnostic significance. Two rare types of spinal fluids sometimes occurred in poliomyelitis when hemorrhagic process had been more than usually extensive. The first of these was of the true hemorrhagic character, the red blood cells being evenly diffused throughout the field. When collected in successive tubes, the specimens were all hemogeneous, showing no change in the intensity of the hemorrhage. This served to differentiate it from bloody fluids obtained by the accidental puncture of a vein. The second of these rarer fluids illustrated the so-called syndrome of Froin. It had the characteristic yellow color, and coagulated spontaneously. The spinal fluid from early cases of purulent meningitis showed a varying degree of cloudiness, except in very rare instances when it might be clear. A greater increase in albumin and globulin was usually found here than occurred in poliomyelitis with a poorer reduction of Fehlings. The cells in these fluids of purulent meningitis were 90 per cent. or more polymorphonuclears, and the etiological organism was found except in the mildest cases. In certain mild cases of meningitis, probably of epidemic variety, the meningococci might never be positively demonstrated in the fluid. In purulent meningitis due to other organisms, these practically always appeared later. In one instance, she had seen a clear fluid from an early case of epidemic miningitis. This was of about eighteen hours' standing. Although the cellular reaction was so slight, the meningococcus was demonstrated to be present in the fluid by smear and culture. The fluid in meningism was increased in amount but practically normal in character. When seen a week or more after the onset, cases of poliomyelitis, especially if presenting cerebral symptoms, must be differentiated from tuberculous meningitis. The spinal fluid in both these conditions was clear, and increased in amount. The albumin and globulin content of both was also increased; but usually in poliomyelitis the increase of both these last-named elements was not so great as occurred in tuberculous miningitis. The reduction of Fehling's solution was usually better, and Dr. Neal said that many tuberculous fluids gave a good reduction of Fehlings though the contrary had been stated. The cellular element was also usually less in poliomyelitis. In both conditions, at this stage, there was ordinarily a mononucleosis, although in some acute cases of tuberculous meningitis there was a polymorphonucleosis. If, however, as might occassionally happen, the increase of albumin and globulin was greater than usual, and the reduction of Fehling's solution was not so prompt, then the determination of the disease must wait upon the results of animal inoculation if it had been impossible to demonstrate tubercle bacilli in fluids. In brief, then, a spinal fluid increased in amount, and showing a slight to moderate increase in albumin and globulin, a good reduction of Fehlings, and a varying cellular increase, mostly mononuclear, made the diagnosis reasonably certain in fairly early cases of suspected poliomyelitis. A slightly cloudy fluid occurring very early in the disease must be differentiated from a similar fluid in an early purulent meningitis. Fluids from the cerebral or encephalitic type of poliomyelitis sometimes might be differentiated from fluids of tuberculous miningitis only by animal inoculation.

The Importance of the Present Epidemic.—Dr. HAVEN EMERSON said that the Health Department was not able at the present time to present statistics in a complete form. The records showed the date on which the cases were reported, and not the date of onset. For instance, in May only five cases were reported; since May, fifteen additional cases had been reported that had their onset in May. In June, the incidence of the disease rose rapidly. The increase in the number of cases was observed about June 20, and rose rapidly until July 11, when the highest point was reached. Since that time there appeared to have been a recession, but it could not be said, as yet, that it was permanent. Dr. Emerson presented the statistics for diphtheria, scarlet fever, measles, and diarrheal diseases during the past six years, and the first six months of the present year, for New York City, and contrasted them with the number of cases and deaths reported from poliomyelitis. They showed that both the morbidity and mortality rates of poliomyelitis were low in comparison with the abovementioned diseases. During the first six months of 1916 there were 884 deaths from diarrhea and 57 from poliomyelitis. The community looked with complacency on the former while it was panic stricken in the presence of the latter. The psychological state of the lay public was interesting at this time. The panic that had resulted from reports with reference to infantile paralysis was probably due to the fact that this was the first epidemic of this disease in which it was reportable in New York City. It was also the first time that there had been a concerted effort at hospitalization of the disease. The present method was frankly an experiment. At the onset the Health Department was confronted with two alternatives. The one was to attempt quietly the medical control of the cases; the other was the method of publicity. They had decided in favor of the latter as offering the better prospect of real control of the disease. This method also offered the opportunity of giving the city a lesson in cleanliness and the control of infection. This was the first epidemic of poliomyelitis in this city that had been studied while it was in progress. The epidemic of 1907 was not studied until in November, when the Neurological and Pediatric Sections of the New York Academy of Medicine appointed a committee to investigate that epidemic. In that epidemic there were probably 2,500 cases. The average mortality, as estimated in foreign epidemics, had varied from 7 to 10 per cent. During the epidemic of 1907 the mortality was 5 per cent. During the present epidemic about 2,600 cases have been reported. Investigation showed about 1,600 of these to be true poliomyelitis. The mortality thus far in this epidemic was estimated to be 18.7 per cent. The most important factors in dealing with infantile paralysis were early diagnosis and the institution of methods by which they were able to prevent the spread of the virus among the healthy, and putting all cases under neurological and orthopedic observation. This might save the individual and the public from the future burden that permanent crippling implied. Infantile paralysis was essentially a disease of early childhood. At least 99 per cent. of the children affected had been born since the last epidemic. Of the cases of true poliomyelitis reported it was estimated that 917 have been under five years of age, and that 99 per cent. have been under ten years. About 403 cases have shown paralysis. In 50 per cent. of the cases the paralysis made its appearance in the course of a few days after the onset of the disease. The longest period after the onset at which paralysis made its appearance was sixteen days.

In from 5 to 8 per cent of the cases, secondary or subsequent cases have occurred in the same family. When one gets a second or third case in the course of three or four days after the onset of the first one it is safe to classify it as a secondary case. These facts were important, since the public had not previously been impressed by the infectious nature of the disease. The person suspected of being a carrier of infantile paralysis presented a difficult problem, since they could not prove definitely that a person was a carrier, as could be done in diphtheria or typhoid fever. This epidemic has also presented the opportunity for concerted action on the part of hospitals. This would probably result in some definite plan for dealing with such emergencies in the future that would greatly benefit the public and would favor scientific study of the disease. The experience in this epidemic had shown the necessity of having a staff suited to meet the needs of cases of infantile paralysis. Dr. Emerson said he would like to urge that hospitals that were likely to have cases of infantile paralysis organize a staff consisting of a laboratory diagnostician, an orthopedist, a neurologist, and a pediatrician. There would be a great field for social-service work for many years to come among these patients. There was another point of importance in connection with this epidemic, and that was that it had shown the extent to which medical men would sacrifice themselves and their financial interests to the public welfare. Many instances had come to his knowledge where physicians who had been taking care of these cases of infantile paralysis had, for the time being, lost their practices, and were actually suffering in consequence, their patients being afraid to come to their offices. Other physicians should do all in their power to discourage this attitude on the part of the patients and to see that such physicians did not suffer because of their willingness to sacrifice themselves. Finally, it should be remembered that no health department, however efficient, could control an epidemic and secure proper police enforcement of its regulations without the support of the medical profession. There must be early diagnosis and a willingness to report cases, and it was to be hoped that as a result of this meeting many undetected cases would be promptly reported to the Department of Health.

Dr. William H. Park said that Dr. Flexner and Dr. Noguchi had added so much to their knowledge of infantile paralysis that there was little for him to add. He would like, however, to emphasize one or two points along the same lines that Dr. Flexner had spoken. At the present time they knew that the sick person was the source of most of the contagion, and that the persons in attendance to the sick person, or the carrier, spread the disease. There was no known carrier, as a fly or insect, but the fly or filth that had been contaminated by the sick person or the carrier might spread the infection. If an insect was found to convey the contagion, it would probably be in a subordinate degree. If we could detect the carrier of poliomyelitis as we can the carrier of diphtheria or pneumonia or typhoid fever, we would not act much differently than we were doing. We possessed the knowledge necessary for the detection of diphtheria and pneumonia carriers, and yet we had done but little to control these diseases by control of the carriers. From what had been done in other lines it was possible that more might be done in the treatment of poliomyelitis by vaccines and serums, but at the present time Dr. Park said he had no new knowledge to offer. They had just begun to study and work along this line, and possibly six months from now they might be able to announce some new discoveries.

Dr. Walter B. James said that two questions had been asked. Some one asked whether it was safe to admit and treat cases of infantile paralysis in a general hospital. A doctor from an infected district asked what the modern treatment for poliomyelitis was.

Dr. Haven Emerson said that it was considered perfectly proper to treat these cases in a general hospital. Experience had shown that in hospitals where sanitary precautions were strictly carried out, infection did not take place. The doctors, nurses, and attendants in the hospitals did not contract the disease.

Dr. Henry Koplik said it was very difficult to speak about the treatment of a disease the cause of which was still under investigation. The treatment of the disease could at this time be only symptomatic. The patient should be isolated and kept absolutely quiet. This was most important. Any one in attendance on the patient should wear a gown and cleanse his hands after leaving the patient. Together with absolute quiet, the patient should have plenty of fresh air and an easily assimilable diet. The bowels should be attended to. Dr. Koplik said he had no particular remedies except those supposed to have an effect on the general nervous system. Liberal doses of urotropin had been employed, but the utility of this drug had not as yet been definitely established. Lumbar puncture offered certain advantages. In the first place, the mere mechanical removal of a certain amount of toxic spinal fluid might be of some benefit. In the second place, it gave an opportunity to make a diagnosis; and in the third place, it relieved pressure. This was of benefit because the fact that we got the Macewen sign showed the presence of pressure. If paralysis started in the patient's limbs, they should be kept absolutely quiet, and in some instances a cast might be applied to prevent contracture of the muscles. When the case was removed it could sometimes be seen that it had been instrumental in diminishing contracture. This contracture might return later when the patient should be referred to the orthopedist. Chloral and bromides might be administered for symptoms referable to the nervous system. Opium should not be used unless absolutely necessary. Charcot had recommended the intramuscular injection of strychnine as soon as the pain and fever had stopped. One-fortieth of a grain might be given daily for thirty days, different groups of muscles being selected for the successive injections. Many cases, however, had regained their power without the injections, and many did not, so that it was very difficult to give an accurate judgment as to their value. Warm baths sometimes proved a great blessing, if they could be given without moving the patient too much. Massage sometimes seemed to aggravate the condition; in other instances it seemed to relieve the pain. Iodide of potassium in large doses seemed to relieve the pain to a grater extent than any other remedy. In a few cases its effect was almost miraculous. There should not be too much activity in the treatment of these cases. No attempt should be made to increase the tonicity of the muscles until the active stage of the disease was passed.

Dr. Leon Louria said there was nothing to be said that had not been laid before them. He wished, however, to emphasize what had been said with reference to the cases that did not show paralysis. The epidemic could only be stopped by a recognition of the cases that did not lead to paralysis. In a few instances he had noticed a very interesting occurrence. A child would be taken ill with indefinite febrile manifestations, sore throat, and general malaise; he would be treated by the usual remedies for such conditions, and would apparently recover. In the course of three or four days the symptoms would recur, and one would also get definite symptoms of poliomyelitis and definite paralysis. If the disease was recognized early, and the child placed in bed and given the rest that the nervous system required, and the nervous system was not exposed to additional trauma, the virus would not exert as great an effect. The same treatment should be applied to the abortive form of the disease as was given the paralytic form and in this way the development of paralysis might be prevented. In two instances which had come under his observation the disease appeared to be of the abortive type and two weeks later the symptoms became more severe and a definite paralysis with permanent deformity resulted. Scientists were agreed that infantile paralysis was carried from the sick to the healthy child. It was possible for a healthy person to travel into an infected district, to be contaminated with the virus of infantile paralysis and then to implant it in another locality. Children who were slightly ill and whose illness was not properly interpreted were a prolific source of this disease and if they were assembled this evening that they might be prepared to assist the health authorities in their endeavor to control this disease, medical men should be called upon to make an early diagnosis and not to take lightly those ailments that might be abortive types of poliomyelitis.

Dr. Samuel J. Meltzer said that the several papers presented failed to cover one essential phase and that was the treatment of the disease. The reason for it was to be found, perhaps, in the discouraging fact that there was, at present, practically no treatment for poliomyelitis. He wished to bring forward three promising therapeutic measures based essentially upon personal work. Since he had only five minutes at his disposal, his remarks must of necessity be dogmatic and very brief. His practical suggestions had to be introduced by the following considerations. Any inflammatory focus

was surrounded at the periphery by zones of hyperemia, exudation, and edema. Thirteen years ago, in experimenting upon rabbits' ears, he found that an injection of adrenalin reduced the entire inflammatory swelling to a very small focus in the center, consisting mainly of paralyzed blood-vessels (passive hyperemia). The peripheral zones of edema and active hyperemia disappeared completely for some time. Several years ago Dr. Auer and he found further that an intraspinal injection of adrenalin into monkeys produced a long-lasting effect upon the blood pressure, longer than by any other method of administration; more than one hour might pass before the blood pressure returned to normal. On the basis of these observations and on the further plausible assumption that the early stages of the paralytic effects in peliomyelitis were not caused by the chief inflammatory focus but by the peripheral zones of active hyperemia, exudation, and edema, he induced Dr. Clark, then working under Dr. Flexner at the Rockefeller Institute, to make the following experiments. Monkeys dying from experimental poliomyelitis received intraspinal injections of adrenalin. The beneficial effect was most striking. Animals which were paralyzed and moribund at the time of the injection were seen several hours later eating bananas which they held themselves. The paralytic conditions were strikingly improved and the life of the animal was prolonged in some cases for several days. The animals finally died; but in this series of Dr. Clark's experiments, all had received *reliably fatal* doses of the virus. It was important to bear in mind that the mortality in human infantile paralysis was generally not more than 25 per cent. and was usually due to respiratory paralysis. It was probable that often the respiratory paralysis was not produced by the chief inflammatory focus, but by the preceding extensive peripheral zones of exudation and edema, which were surely capable of interfering with the vitality of the nerve centers controlling respiration. If the exudation and edema could be removed for some time, the lives of a few or of many of the cases might be saved, for it frequently happened that the ascending progress of the actual inflammation came to a standstill. On the basis of these facts and considerations he recommended the injection of adrenalin intraspinally in every case of infantile paralysis, the injections to be repeated in from four to six hours. The procedure might save life, and in surviving cases it might reduce the extent of the final lesion. There was no danger in this procedure. Monkeys stood well as large a dose as 2 c.c. in a single injection. However, in human infantile paralysis the injections should be begun with a dose of 0.5 c.c. of adrenalin, until more was learned about the effects. There were two other suggestions he wished to make. One was to administer artificial respiration by means of his apparatus for pharyngeal insufflation as soon as the patient showed a degree of unconsciousness and respiratory insufficiency. It was an easy and reliable procedure. The second suggestion was to administer oxygen under pressure in a respiratory rhythm by an apparatus which he had recently devised and used on human beings in several instances. It abolished rapidly cyanosis and might save life. It might even act specifically on the virus of poliomyelitis.

MEDICAL SOCIETY OF THE STATE OF NEW JERSEY.

One Hundred and Fiftieth Annual Meeting, Held in Asbury Park, June 20, 21, and 22, 1916.

(Special Report to the MEDICAL RECORD.)

(*Concluded from page 125.*)

Wednesday, June 21—Second Day.

Reception of Delegates and Guests from Other States with Responses by Presidents of State Societies and Delegates from Other States.—Dr. W. W. PALMER of Boston, President of the Medical Society of the State of Massachusetts, said he was not prepared to make a formal address, but would present the greetings and congratulations of the Medical Society of the State of Massachusetts, which was fifteen years younger than the Medical Society of the State of New Jersey, having been organized in 1781. The charter of the Massachusetts Society bore the names of Samuel Adams and John Hancock. There were records showing that Dr. Chrystopher Elmer of the New Jersey Society had written to Dr. John Warren of the Massachusetts Society asking him for a copy of the act of incorporation of the Massachusetts Society. While the Medical Society of the State of New Jersey had been organized longer than that of Massachusetts, the latter was the first to have been incorporated by an act of Legislature. The records of the Massachusetts Medical Society had been collected and published by Dr. Henry I. Bowditch and made very interesting reading. In closing, Dr. Palmer said that not only was the Medical Society of the State of New Jersey ancient and honorable, but it had many honorable members who had been in the practise of medicine for more than fifty years. He had just met such a man who told him that he had practised medicine for fifty years and that without a vacation; the society should appoint a conservation committee who should see that he and others of his kind were compelled to take a vacation.

Dr. H. B. EARLE of Greenville, South Carolina, said he accepted the invitation to be present not only in order to congratulate the members of the Medical Society of the State of New Jersey on the attainment of so venerable an age, but to see how the oldest medical society in the United States conducted its affairs. The Medical Society of the State of South Carolina was one of the youngest in the country, having been in existence only six or eight years, but they were doing good work. While South Carolina had not had a State medical society it had produced some famous medical men, Marion Sims, Chisholm, and Thomas. In their society they had been having fifty or sixty papers and holding their meetings until late at night. He thought the custom of the New Jersey Society of having fewer papers, having them of a high character, and placing emphasis on the social side was worthy of emulation.

Dr. EDWARD Y. DAVIDSON of Washington, D. C., President of the Medical Society of the District of Columbia, after expressing his appreciation of the depth and wholesomeness of the hospitality that the guests had received at the hands of the society, said that the history of the Medical Society of the State of New Jersey overlapped that of the United States; it antedated by ten years the birth of this republic and had given great men who had contributed to the making of the history of this republic as well as having been an important factor in American Medicine. The society was born of hardy parentage bred on ruggedness in a critical period and it was to be expected that their offspring would carry out the high mission which they had undertaken for the advancement of medicine. They were to be congratulated not only for their seniority, but for their high achievements in medicine.

Dr. J. R. BROWN of Tacoma spoke for the Medical Society of the State of Washington. He said that the Medical Society of the State of Washington was one of the youngest State societies, but was proud to boast of its youth. They would hold their twenty-seventh annual meeting next month. There were at the present time 1,500 physicians in the State of Washington and 900 were members of the State society. They were organized on practically the same lines as the New Jersey State society. Some of the work they were doing might be of interest. Washington was a manufacturing State and there were many accidents, and they had come to the conclusion that it was advisable to have an accident insurance. Formerly the doctors had many damage suits as the results of fractures and other injuries; now the employees received compensation and there few damage suits. The doctors had combined for protection and had a medical defense fund against malpractice suits. There had been more than 100 suits and in none had a judgment been secured against a physician. This had been a means of unifying the medical profession so that they now stood practically as one man. Every three years the physicians of Washington, Idaho, and Oregon met together and had formed a great Northwestern Medical Empire which was doing much for the uplift of the medical profession. They had only one first-class medical college for 4,000,000 population and they did not want any more.

Dr. GEORGE I. MCKELWAY of Dover spoke for the Medical Society of the State of Delaware. He said the Delaware society was incorporated in 1789, and he believed it was the third oldest medical society in the United States. He said he had lived in Delaware but a short time; most of his early associations were connected with New Jersey. His grandfather had settled in Trenton where he lived until he was ninety years of age and practiced almost up to the time of his death so that the early conditions of the practice of medicine in this State were particularly interesting to him.

The Morbidity of Childhood and the Mortality of the Second and Following Decades.—Dr. THOMAS N. GRAY of East Orange presented this paper, in which he stated that the success attending the efforts to conserve infant life gave warrant for the exploitation of another line of child welfare work, namely, that of giving the child a chance to grow into robust adult life and to live the allotted years of man. His object in presenting this subject was the prevention of those deaths which occurred in later years due to those diseases of childhood which were preventable through the prophylaxis of non-communicable diseases made possible by proper equipment for diagnosis, thorough foreknowledge and thoroughness of examination and thorough control of epidemics and immunization against communicable diseases. Another reason for the conservation of child life had come to them and that was the vital need for preparedness. The essayist discussed the cause of later year deaths from organic heart disease, chronic nephritis and pulmonary tuberculosis and sought in the diseases of childhood a possible relationship with these, especially with reference to rheumatism, diphtheria, scarlet fever, measles and whooping cough. He said that no figures were extant, showing the percentage of deaths at ages from ten to forty years of age from organic heart disease and nephritis traceable to first decade rheumatism, diphtheria or scarlet fever, but it was known that scarlatinal rheumatism was the cause of many cases of endocarditis and damaged heart valves, that in a child a typical polyarthritic manifestation of rheumatic infection was a common occurrence, that the cardiac complications of rheumatic infection were not only more common in the child than in the adult, but as a rule were more severe. There was a definite connection between heart lesions and "growing pains," attacks of tonsillitis and a history of a fever lasting a week or ten days. His experience which had covered the lives of patients from birth to the fourth decade had demonstrated such a connection many times. It was his belief that a large percentage of deaths in later years from the disease mentioned were due to the preventable diseases of childhood. Many opportunities of forestalling damage to the heart valves were lost through the failure to make an early diagnosis of rheumatism and to follow it by treatment with the salicylates. In diphtheria many physicians waited for the report from the laboratory before giving antitoxin, and too many discarded their suspicions as to the presence of diphtheria on the receipt of a negative report. Until the time came when research workers would place at their command the means for immunization against all infections, and even after it we must look to our health boards to prevent epidemics of scarlet fever, diphtheria, measels, and whooping cough as effectively as they now controlled smallpox. Dr. Gray said he had asked a health officer the following question: "Would not the same isolation, strict quarantine, with immunization in diphtheria and pertussis, limit and control these diseases?" He had also asked whether the health boards did not have the same control over other communicable diseases that they had over smallpox and why, if they had such control, they did not exercise it? The health officer replied: "Because public opinion would not sustain us and it would bring about a furious storm of protest." In discussing the control of tuberculosis, the essayist said that this disease could be controlled only by the removal of open cases to sanatoria and by placing infected children in preventoria. To do this would require an adequate sanatorium and preventorium in every county. There was only one reason for inadequate county sanatoria in this State with its ample enabling act for their establishment, and that was the failure on the part of freeholders to appropriate enough money. This failure was due partly to lack of appreciation of the need and partly to the deterring fear of a raise in the tax rate. Sanatoria without preventoria would lead to an endless chain of expenditure with no hope of controlling the disease. In discussing the problem of bovine tuberculosis the essayist said that the fact that the tuberculous cow remained in the herd was not the fault of health boards, but was due to the injustice of the law which allowed the dairyman but a nominal price for his slaughtered cow and took from him the value residing in hide, hoof, fat, and meat if it was salable.

Dr. JOHNSON of the New Jersey State Board of Health said that the question was often asked why so much attention was paid to infants and so little to the young adult. Dr. Gray had pointed out the need of more thorough examination and diagnosis in the diseases of children and had urged that more care be taken in the reporting of communicable diseases. Dr. Louis I. Dublin had recently published a study of 1,153 cases of scarlet fever in reference to their sequelæ. In this series there were ninety deaths, and eleven of these showed distinct kidney involvement. He found that either the impairments of the kidneys which were so common in scarlet fever were severe enough to cause immediate death, or that in the survivors the injurious effect was not sufficiently great to kill within the next five years. He said that it was quite possible that ultimately there might be an increase in the expected number of deaths from kidney lesions, although such a consequence might not manifest itself until ten or more years had elapsed after the initial incidence of the scarlet fever. Although the sequelæ of scarlet fever were apparently not an appreciable factor in the mortality of the survivors, it should not be overlooked that the disease itself still constituted an important factor in child mortality. Dr. Johnson said she would like someone to express an opinion as to whether there was any relation between nephritis and cold baths, whether it was possible that the intense chilling resulting from cold baths might result in nephritis. She did not believe they could effectively control communicable diseases until they had well trained, full time health officers and good nurses to assist these health officers. It was important that parochial schools as well as public schools should be inspected. The truant officers should also cooperate in reporting communicable diseases. Teachers sometimes kept children in school when they ought not to be there. In Princeton the Board of Health notified the school nurses of every case of communicable disease and the nurses notified the Board of Health of any case they encountered, and in this way a closer watch could be kept over cases of communicable disease. Accurate records as to the prevalence of tuberculosis could not be obtained, but it was estimated that for every fatal case there were eight or twelve living cases. On such a basis it would seem that the hospitals were accommodating only about 3 per cent. of the cases. With such figures it ought not to be necessary to point the moral. The speaker also emphasized the importance of pasteurization of milk as a preventive of bovine tuberculosis and said that all communicable diseases should be as rigidly quarantined as smallpox now was, and then they might be as effectively controlled.

Dr. HENRY H. DAVIS of Camden said they wanted local health boards to do better work, but they did not want the tax rate raised. If there was an epidemic of smallpox they had no trouble in getting an appropriation to control it, yet among all the communicable diseases there was none so easy to stamp out. The great problem in the control of communicable diseases was how to get the money.

Dr. GORDON K. DICKINSON of Jersey City said the dollar was the great thing. When people looked at the dollar and saw the dollar sign on one side and "In God we trust" on the other they decided to trust to God to take care of the contagious disease. It seemed to him that the only thing to do was for the profession to get together and organize, to send out a man of personal magnetism who was interested in this subject to stir up the profession and get them to organize a campaign of education, and then when they asked for an appropriation from the State or a municipality for the control of communicable diseases they would get it.

Dr. ALFRED F. HESS of New York said that Dr. Gray had brought up one of the most important public health problems of the day. It was recognized that most of the ills of adult life were contracted during infancy and childhood. That tuberculosis was the most important of these ills was recognized by everybody since von Behring brought out the facts with reference to the large number of infections with tuberculosis in childhood. Dr. Hess said he happened to be in charge of the first preventorium for infants in the United States. This preventorium was located at Farmingdale, about ten miles inland from Asbury Park. The institution accommodated about 180 to 200 children of tuberculous parents. Their experiment of taking the infants of tuberculous mothers before they became infected might also be of interest. They had been told that it would be impossible to get these babies, as the mothers would not give them up. They had thus far taken twenty-five babies who gave negative von Pirquet reactions; that was, they were taken before they became infected. They took some of these babies from mothers who were in tuberculosis sanatoria. They had

established the fact that the mothers were willing to give the children up. Another problem was with reference to returning the child. That bothered them some at first. In about one-half the cases the mothers had died after a year or so and the children were then returned to a safe home. In some instances the mothers were cured and it was safe to send the babies home. In other instances they kept the children, and these were a problem. Dr. Hess said it seemed to him that this was an important way to attack the tuberculosis problem. Most of the speakers had referred to the financial side of the problem. He had just attended a meeting at Long Branch, a city whose financial budget amounted to $250,000 a year, and last year they gave $25,000 to health work. This year they had a new government and it was decided to cut down the appropriation for health work to $15,000. Finally a compromise was made and $19,000 was decided upon. They did not think a visiting nurse very important, while in reality she was the keystone of public health work because she found out and brought to the doctor's attention the various needs of the individual. If the doctors wanted to organize and do some work, Long Branch was an interesting example which they might take as a starting point.

Dr. JULIUS LEVY of Newark expressed the opinion that they could not affect the problem of tuberculosis in New York to any great extent by a preventorium that took care of twenty-five children. This was only an experiment. He believed real prevention would come not through preventoria, but through bettering living conditions. The effort to control tuberculosis by sanatorium treatment would only present the problem of the continued increase of accommodations in institutions. It was said that nearly everyone contracted a little tuberculosis and everyone is exposed to the disease to some degree, and the problem was to minimize the danger of this exposure. The infant should be left with the tuberculous mother if it could be nursed and at the same time protected from infection. Breast-fed babies were much less liable to contract infection and possessed a higher resistance than bottle-fed babies. This was shown by the fact that there were fewer cases of measles among breast-fed babies, and when they did contract the disease they had it in a milder form. The medical profession should be taught that nursing was possible in 99 per cent. of the cases and that it increased resistance. Some children had a myocardial degeneration due to the fact that they did not get enough rest during an infectious disease. Such a child might not be definitely ill but merely under par. The child might not seem sick enough to put to bed, yet a week's rest in bed was what was needed. This was frequently the case when a child had an infectious disease in a mild form. No matter how mild the infectious disease might be the child should be kept in bed for a week.

Dr. ALEXANDER MARCY of Riverton said that public health work was something entirely different from the practice of medicine. If men to do efficient public health work were wanted they must be trained to that work. In the State of New Jersey every health organization must have a licensed health officer and the State Health Board provided for these examinations by an act of Legislature. Many of the men taking these examinations who had practised medicine knew less about public health work, judging from the results of the examinations, than those who had never studied medicine. They had the cart before the horse; the first thing to be done was to find some way of training men to become sanitary officers. A man who wished to do public health work should go to some institution and take a course and graduate as he did from medical college. The need was for trained sanitarians, trained health officers and trained medical inspectors. As to the medical profession becoming a unit; if that condition could be realized it would be impossible for any body politic to stand before a united profession. They now went before the Legislature with half a dozen men from different parts of the State and nearly every individual had an idea of his own; there was no consensus of opinion and the politicians say, "Great Heavens! there come the doctors and they have not the slightest idea what they want."

Dr. LINN EMERSON of Orange expressed the opinion that what was needed most was sanatoria for advanced and incurable cases of tuberculosis. All sanatoria were conducted on the idea that the percentage of cures was the one thing to be considered, and if an individual was in the advanced stage and could not be cured he was sent home, and the result was that he infected everybody in the family. All the money spent on preventoria was as good as wasted so long as communicable cases were turned loose, and it was a surprise to him that people interested in tuberculosis did not realize this fact when they went about endeavoring to improve conditions.

Dr. HERMAN GROSS of Metuchen called attention to the working conditions in factories which were responsible for a great deal of tuberculosis. He told of one factory where the women went to work early and worked late, working ten and twelve hours daily, and then going home and doing their house work and said that within three years after they began this work 50 per cent. of them came down with tuberculosis. When the inspectors came around the employees were told to tell them that they worked only fifty-five hours a week, which was the limit the law set for women factory workers. Something should be done to limit the working hours and control conditions in the factories. In this factory only ten minutes was allowed at noon. Abroad employees were given an hour at noon.

Dr. B. D. EVANS of Morris Plains said that if anything was to be done of a practical character it would have to begin with a campaign of education; every large project, whether in medicine or law or municipal government or national government, in the sciences, the arts, or the crafts, was brought about by educational work. In a case of measles the doctor too often told the family that the diseases did not amount to anything; that the child should be protected and it was nothing serious. The general public had come to look upon measles as of no more consequence than a slight attack of indigestion. Children should be told of the dangers of measles in the public schools as they were now told of the dangers of alcohol, tobacco, smallpox, and tuberculosis. If the people were made to understand the gravity of the sequelæ of the communicable diseases a public sentiment would be created, and when there was a request from State or local health boards for funds they would be forthcoming. It was right that this society should be behind such a campaign of education.

Dr. THOMAS N. GRAY of East Orange said he agreed with Dr. Levy that the underlying problem was that of economics, but they must deal with present conditions, and if they could not do anything to remedy the economic conditions they must have sanatoria, they must have better isolation and better protection on the part of the boards of health. Tuberculosis was not contracted in the open air but was essentially a home disease. They should have a sanatorium in every county with accommodations for every open case of tuberculosis, but he wished to emphasize what he had said, that sanatoria without preventoria would never stop the spread of tuberculosis.

Reception of Delegates.—Dr. MARTIN I. TINKER of Ithaca, President of the Medical Society of the State of New York, spoke for that organization. He said that in listening to the discussion he had come to the conclusion that the state societies did not differ essentially from one another. He had hoped to learn something of the organization and methods of the New Jersey State Society. The New York Society did not have all that was good in organization; they had much to learn from other societies. Progress in medicine was not the work of a few brilliant men; progress did not come from a community where the average intelligence was low but where the average standards were high.

Pennsylvania Delegation.—Dr. CHANDLER then welcomed the twenty-five delegates from Pennsylvania.

Dr. JOHN MCLEAN of Philadelphia, President of the Philadelphia County Medical Society, said he believed the Philadelphia County Medical Society was the largest county medical society in this country. They had done their part in influencing education. They were not obstructionists but constructionists and when they went before a governing body they knew what they wanted and they went with definite recommendations.

Dr. E. A. CRUEGER of Philadelphia said the problems confronting health officers were complex and perplexing. It was very hard to make families recognize that the rights of the individual ceased where the rights of society began. Mention had been made of the relationship of legislative bodies to health departments. He thought a great deal could be done by diplomatic procedure and here the first step was the education of public sentiment. He told of some of the difficulties that Philadelphia had encountered in getting proper hospital accommodations for tuberculous patients and for the insane and the struggle they had encountered in get-

ting a new municipal hospital so that they wanted to sympathize with the New Jersey Society in its trials and to share in its triumphs.

Dr. WILLIAM DUFFIELD ROBINSON of Philadelphia told of the intensive health work they were doing in Philadelphia. They took one block at a time and made a study of every individual in that block and kept records. They had proved that the intensive method of doing public health work was the most effective. They had physicians, visiting nurses, social workers and all the newer methods and they were getting better results in this way.

Address of the Third Vice-President.—Organotherapy. Dr. THOMAS W. HARVEY of Orange, N. J., delivered this address. He stated that many tissues of the body had internal secretions, that was, they elaborated during the process of metabolism, either in response to stimuli from the central nervous system or excitant agents from the secretions of their tissues, a substance which they poured into the blood stream and which had important functions in the body. Certain internal secretions were essential to the maintenance of life, notably that of the suprarenal capsules and the pituitary body. These regulated the amount of blood supply, determined growth, inaugurated chemical changes in the body necessary to nutrition, stimulated phagocytosis, antagonized infections, and antidoted toxins that resulted from errors in the chemistry of life. Extracts of internal organs did not represent the entire effect of the internal secretions that were elaborated in these glands. The ductless glands were all interdependent. When there was a deficiency in some ductile gland it was often impossible to determine which one and often the same symptom complex found threatening life was traceable to deviation from the normal of quite dissimilar organs. The essayist had seen cases of status lymphaticus in which recovery took place from very serious attacks and the subsequent history indicated the involvement of other organs than the thymus; one patient was found to have Addison's disease, and another Graves' disease. There seemed to be no success attendant upon the use of adrenalin in Addison's disease associated with lesions of the suprarenal capsule. From the use of the secretions of the ovary much could be expected in the amelioration of disturbances of the nervous system consequent upon the establishment of the menopause whether natural or artificial. It was well in the present state of our knowledge to accept the terms "hyper" and "hypo" as expressing different forms of disease caused by disturbance of function of these glands without committing oneself to the theory that there must be an excess or a deficiency. Thymus extract was useful in many cases of exophthalmic goiter, particularly those occurring about the period of puberty. The writer discussed the relationship of the pituitary gland to abnormalities of growth and development and called attention to the usefulness of this agent in obstetrical practice and after laparotomies. In pneumonia pituitary extract might be used as adrenalin had been to sustain the heart and circulation during the crisis. It was also useful in shock, surgical or emotional. Thyroid extract had a number of indications. It was useful in obesity, though injudiciously administered it might be productive of harm. In arteriosclerosis it lowered blood pressure.

Oration in Medicine — The Classification, Prognosis, and Treatment of the Nephritides.—Professor MARTIN H. FISCHER of Cincinnati presented this communication which was illustrated by graphic charts and brought out several new ideas in reference to nephritis. He stated that the effect of water and sodium chloride in nephritis could only be determined with authority on the basis of the cause of the clinical entity called nephritis. It might be said that nephritis was an edema of the kidney and this brought up the problem as to the cause of the edema of the kidney, which might and did affect other organs and tissues as well as the kidney. The question might be asked: "Why do the cells and tissues of the body hold any water at all?" "Why does the body hold so constant an amount of water from month to month and from year to year?" Even the osmotic theory lacked a good many facts to support it. One must get at the laws that governed the absorption and excretion of water by simple colloids, and of these the protein colloids were the most important. They had found that the more acid that was added to a protein colloid in the presence of water the greater the degree of swelling, and that if this acid was neutralized one got a shrinking of the protein colloid. If to the protein colloid swollen by acid solution any salt was added there resulted a reduction of the swollen fibers. Sodium chloride had less activity in this respect than other salts, such as sodium nitrate, sodium acetate, etc.; the most powerful salts were sodium tartrate, sodium citrate, and sodium sulphate. Magnesium sulphate was very much more powerful than the same concentration of sodium or potassium. The action that this agent had in extracting water from the bowel was well known but the explanation had been lacking. If an ox's eye was placed to soak in an acid solution an experimental glaucoma was produced; the eye would become swollen to the point of rupture. If one then added sodium citrate to the solution the eye would shrink. Glaucoma was entirely an edema of the eyeball. Tissues suffered changes accordingly as they held more or less water and the amount of water sucked up was determined by the cells themselves and not by something outside. If one applied these facts to nephritis which was an edema of the kidney the general conclusion would be reached that nephritis was also a composite of a number of chemical changes occurring in the whole or in parts of the kidney; they were all due to a common cause, namely, the abnormal accumulation of acids or other substances that acted like acids, urea, etc. This having been proven one ought to be able to do something for the nephritic patient. The evidence of the accumulation of acids in nephritis was well established and when there was a sufficient acid concentration albumin, casts, and blood appeared in the urine. If water was ingested it was retained and one got edema and thus one saw developed parenchymatous nephritis. It was well known that muscular contractions during violent exercise produced lactic acid and when violent exercise was continued the acids accumulated faster than the blood could oxidize them and one would find albuminuria with casts. In some instances in young healthy athletes as much as several grams of albumin to the liter had been found after violent and prolonged physical exercise. The same thing might be observed in warm-blooded animals after exposure to cold. In considering nephritis one should not concentrate his attention on the kidney but should look outside for the principle that should guide him in the treatment of nephritis. The cause of the abnormal production of acid must be sought. One might have a patient with pneumonia and convulsions due to the large amount of acid produced in which one could not neutralize the acid for hours after the convulsions. Again about 50 per cent. of the eclampsias occurred, not during, but after delivery, this being due not only to the accumulation of acids before delivery but to the additional accumulation due to the muscular contractions and strain during labor. In such cases one had an acidosis and the indications were for the administration of alkalies and also for the administration of salts in more than physiological concentration. A third rule was to give sugar; a high concentration of sugar also dehydrated. A fourth rule was to give water but this was not an unmixed blessing; there should be enough alkali and salt to neutralize the effect of the water. The idea had been prevalent that to administer salt to a nephritic was to kill him; this was incorrect, and sodium sulphate possessed advantages over sodium chloride. Dr. Fischer objected to the elaborate classification of nephritides in vogue and stated that so little was known of the physiology of the kidneys that there was no warrant for such classification. The kidney was all parenchyma and therefore there could be only one kind of nephritis and that was parenchymatous nephritis. There might be two varieties of parenchymatous nephritis, general and "spotty." That was the entire kidney might be involved or the process might go on in small foci of infection. In the latter condition after the acute attack the prognosis was good in nephritis due to infection, anesthesia, etc. The prognosis on the other hand was much less favorable if the condition of the kidney was dependent upon arteriosclerosis, the reason being that one was dealing with necrosis of an irremovable and irremediable type. When a patient with parenchymatous nephritis developed general edema the idea was that the edema was due to a cessation of kidney function. This was wrong, for the operative removal of a kidney did not produce edema. Edema was not due to loss of kidney function but to something that produced the disease, to a general toxemia affecting all the tissue cells, including the cells of the kidney. The symptoms that had been attributed to the kidney were signs and symptoms of edema of the brain, an intoxication by the same poison that had affected the kidney. The headache of so-called uremia told us that the brain was swollen to the danger point. It was not true that high blood pressure was a conse-

quence of kidney disease; high blood pressure was dependent upon the cardiovascular system and was a compensatory mechanism.

The following questions were asked: "In the use of organic acids of fresh fruits do the acids oxidize to carbonates? In glaucoma should one use the citrates to control the edema? What effect had the intravenous injection of colloidal sulphur? What is the diet in the condition known clinically as chronic interstitial nephritis? What would be your treatment for so-called uremia? Has the Karell treatment any advantages? Is a blood pressure of 140 normal in a man of sixty years? If we use dextrose does it prevent the oxidization of the tissues of the body? What do you mean by a clinical uremia? Does a child make a complete recovery from the nephritis of scarlet fever? Is there any permanent damage from the violent exercise indulged in by athletes?"

Dr. FISCHER, in closing the discussion, said that organic acids were of two types; one type was readily oxidizable and fruits containing this type led to a decrease of water. This was true of most fruits and vegetables, with the exception of strawberries, cranberries, and grapes. On the whole, fruits and vegetables made for alkalinity and not for acidification. In twenty-two cases of nephritis investigated, nine were due to an underlying arteriosclerosis and as a rule the prognosis of these cases was bad. He could not answer the question with reference to the effect of colloidal sulphur. This was a suspension and did not come in the group studied. As to the diet in so-called chronic interstitial nephritis he said he supposed the one who asked that question meant the condition associated with cardiac hypertrophy and vasomotor disturbance. They did not confine these patients to an extremely limited diet but gave them rest and decent food, not merely slop foods. He allowed the patient to eat vegetables which yielded about 25 per cent. alkali, a certain amount of meat was permitted, and enough alkali was administered to keep the urine neutral. As to the treatment of uremia, he did not call the condition uremia; he called it edema of the brain due to a toxin or to a cardiovascular condition. All edemas did not have the same mechanism and one must get at the mechanism in each case. The question was asked as to the advantages of the Karell treatment. This treatment was based on the reduction of sodium chloride and restriction of the intake of fluid, 500 c.c. of milk being allowed daily. The loss of fluid through the lungs and skin was so much more than through the kidneys that he did not think the restriction of fluid made a great deal of difference in the amount of fluid retained in the body, while the restriction of fluids favored the accumulation of toxins. The edema was not due to lack of secretion on the part of the kidneys. He gave alkali and salt to cause dehydration and allowed water, but the effect of the water was controlled by the alkali and salt. A blood pressure of 140 mm. was high. When in any man past the age of forty years the blood pressure went above 130 it was time for him to look after himself. Dextrose did two things. Many of these patients were sugar starved and where there was sugar starvation one got acid intoxication. Dextrose dehydrated as did the salts but in a different way. It was quite impossible to analyze the clinical case that had been referred to, but dyspnea meant increased hydrogen ion concentration and probably edema of the brain; whether this was secondary to an aortic lesion in the case cited could not be stated. When one had acidosis, dyspnea, and clinical edema, the case was not a uremic but a cardiovascular one. In scarlet fever the toxin that caused the kidney lesion was not carried over; there were no traces of such an occurrence, but there might be a lowered resistance and one might get a reinfection of the kidney and a new attack of nephritis with a new organism. As to the danger from violent exercise, football and rowing matches put too great a strain on the process of oxidation. If such work was done regularly it could be carried on all right. The Chinese coolies all had clinically hypertrophied hearts and went through life comfortably with them, but it was different where the strain was temporary; after the strain was over the individual lapsed into a less active life, took on flesh, and degeneration followed.

Election of Officers. — The following officers were elected to serve during the ensuing year: *President*, Dr. Philip Marvel of Atlantic City; *First Vice-President*, William G. Shauffler of Lakewood; *Second Vice-President*, Dr. Thomas W. Harvey of Orange; *Third Vice-President*, Dr. Gordon K. Dickinson of Jersey City; *Recording Secretary*, Dr. George N. Gray of East Orange; *Corresponding Secretary*, Dr. Harry A. Stout of Wenonah; *Treasurer*, Dr. Archibald Mercer of Newark. *Delegates to the American Medical Association*, Drs. William S. Lalor of Trenton and Luther M. Halsey of Williamstown.

The Banquet.—The banquet given on the evening of June 21 was the most largely attended of any in the history of the society. At that time letters of congratulation and felicitation were read from President Woodrow Wilson and from the presidents of many of the State societies who were unable to be present. The treasurer of the society, Dr. Archibald Mercer of Newark, was presented with a loving cup as a testimonial of appreciation of his services to the society during the twenty-five years he had been treasurer.

Thursday, June 22—Third Day

After the completion of the work of the House of Delegates and the inauguration of the incoming President, Dr. Philip Marvel, the morning was given over to the Centennial Exercises of the Essex, Middlesex, Monmouth, Morris, and Somerset Component Societies.

Dr. ALEXANDER MARCY, SR., of Riverton, who had attended the Centennial of the Medical Society of the State of New Jersey and had attained the ripe age of 87 years, was introduced to the members of the Society and congratulated them on the progress they had made during the past fifty years. Representatives from each of the above societies reviewed the early history of his society and gave such reminiscences as he could find of the organizers of these societies. The Essex was the oldest county society in this country, having been organized June 4, 1816. Its charter members were Peter I. Stryker, Ferdinand Schenck, William McKissack, James Elmendorf, William D. McKissack, August R. Taylor, Ephraim Smith, Moses Scott and Henry Schenck. The other counties above mentioned all organized within a very short time after the Essex County Society in response to an act of the State Society requesting such organization. The history of these societies showed that they had been interested in the suppression of quackery, in the elevation of the standard of medical education, in the study of diseases that seemed to be epidemic in their midst, and in elevating the standards of the profession. That they took these societies very seriously was shown by the fines imposed for absence from meetings.

The Disease Carrier on Train and Steamboat.—Wilbur A. Sawyer cites certain reasons for increased disease incidence in travelers. One of these is increased contact with healthy disease-carriers. As these men travel, infection cannot be traced to them. Contact is closer and objects of common use are handled in rapid succession. The abolition of the common cup has doubtless prevented considerable morbidity. Diphtheria has been spread on shipboard by a carrier, or at least numerous carriers were identified during the epidemic, and cerebrospinal meningitis in like manner. In both cases the vessels were overcrowded. These were isolated instances, perhaps, but typhoid carriers are almost ubiquitous. For every 100 cases of typhoid which survive, 7 are reckoned as carriers. On trains the chief danger is in the dining car service, as both cooks and waiters may convey the disease, but on shipboard the carrier is more dangerous—not only cooks and waiters, but stewards, stewardesses and others are a source of danger. This has been realized in lumber steamboats, in which an ordinary passenger acted as carrier. The men drank from the water cask from their cupped hands.—*Journal of Sociological Medicine.*

Prognostic Significance of the Urine in Puerperal Infection.—Schaefer states that after the temperature becomes high in puerperal infection the urine will be found of high specific gravity, dark colored and containing in solution indican and ethereal sulphates. If we can cause the disappearance from the body of all the phenol derivatives, the prognosis should improve. Catharsis and diuresis are indicated, and the density of the urine may be brought down below 1015. A low density, when associated with high temperature, is in itself a good prognostic, and the eliminant treatment will not be required. The obstetrical or rather surgical management, of course, goes ahead as usual, but the author believes that the bacillus coli communis plays a great rôle as a determining cause, and that intestinal hygiene and sanitation must be guaranteed in all puerperal disorders.—*The Medical Fortnightly and Laboratory News.*

NITROUS OXIDE-OXYGEN, THE MOST DANGEROUS ANESTHETIC.

BY J. F. BALDWIN, M.D., F.A.C.S.,

COLUMBUS, OHIO.

SURGEON TO GRANT HOSPITAL, PROFESSOR CLINICAL SURGERY, OHIO STATE UNIVERSITY.

WHENEVER any new line of treatment is proposed it is universally recognized as incumbent upon its sponsors to show that it is better than prevailing lines of treatment, its superiority consisting in a larger percentage of cures, a more prompt recovery, or a diminution of morbidity.

This rule most certainly should apply to the introduction of any new anesthetic agent. Chloroform has its advocates, and for certain purposes its advantages, but ether may be accepted as the standard of safety the world over. Every new anesthetic must, therefore, be weighed in the balance with ether.

If the sponsors of the new anesthetic are actuated purely by scientific motives, every unsatisfactory experience, and certainly every death, would be promptly reported, so that the profession at large could judge as to the relative value of the new anesthetic; while if such adverse experiences are not reported, but attempts are even made to cover up and deny their occurrence, then only mercenary motives can be attributed to the advocates. Teter of Cleveland, in a personal letter, reports that he knows of twenty-six nitrous oxide-oxygen fatalities, nine of which have occurred in Cleveland. Dr. A. H. Miller of Providence, R. I., has collected references to eighteen deaths. Rovsing was able to get track of thirteen deaths, several of which had been suppressed. (This author[1] in his chapter on anesthesia gives a death rate of one in 2,000 for chloroform, and one in 50,000 for ether.) Gwathmey (personal communication) knows of from twenty to forty unreported deaths.

Practically all of the anesthetists who have written on nitrous oxide-oxygen state most positively that death occurs *only* from asphyxia, and that if the anesthetist watches the color and pushes the oxygen death cannot occur. If that is the case, it is certainly very important that the anesthetist shall know what are the symptoms that indicate asphyxia. Turning to Gwathmey[2] (p. 134) we find the following statement: "The fourth stage, or stage of overdose, supervenes through some error of technique by which asphyxia becomes the predominant feature of the narcosis. Breathing becomes embarrassed usually through convulsive muscular spasm. The interference with respiration is first marked through hyperpnea (excessive breathing), then by dyspnea (difficult breathing). Violent or convulsive expiratory efforts, sometimes accompanied by general muscular spasms, mark the second stage of asphyxia. Following this there is a stage of exhaustion, in which the muscular spasm is superseded by muscular flaccidity. The pupils become more widely dilated, the lids are widely open, the conjunctivæ are insensitive, the pulse becomes imperceptible, respiration is marked by prolonged sighing inspirations which gradually cease. Paralysis of the respiratory center is complete and death supervenes. Marked cyanosis accompanies this condition of affairs."

In none of the cases detailed in this paper was death the result in any way whatever of asphyxia, but in all of them the death occurred without warning, in the midst of an apparently smooth anesthesia, and with the startling suddenness of an overdose of chloroform.

Gwathmey states, as the natural effect of nitrous oxide-oxygen administration, that the pulse becomes rapid, from 140 to 160 per minute, and in prolonged operations the temperature goes up from ½ to 2 degrees (p. 109).

According (Gwathmey) to the experiments of Buxton, and later of Wood and Cerna, "nitrous oxide-oxygen exerts a direct action upon the heart itself, having little or no direct influence upon the vasomotor centers of the brain cortex" (p. 130). "Buxton . . . found that . . . nitrous oxide produced so great an enlargement (of the bulk of the brain and the cord) as to force out the cerebrospinal fluid" (p. 131).

"The most natural inference, from the study of the reflexes and other effects upon the nervous system, is, according to Kemp, that nitrous oxide acts especially upon the brain cortex" (p. 131).

It is inconceivable to think that any agent capable of producing the constitutional disturbances indicated above should not be pregnant with manifold possibilities of evil; and yet, in a calendar just received from a manufacturer of nitrous oxide-oxygen, we are told that this combination "Does not affect the heart; does not affect the kidneys; does not produce nausea; decreases danger of postoperative pneumonia."

Connell,[3] who writes the article on anesthesia in Johnson's new work on "Operative Therapeusis," says of the nitrous oxide-oxygen anesthesia that "since the extensive introduction of this gas into general surgery, the reported and unreported deaths have probably far exceeded those from ether," and aside from its death rate it is evident from his entire chapter on this subject that he regards its disadvantages as far outweighing its possible advantages.

Luke, anesthetist to St. Luke's Hospital, New York, reports[4] one death out of about 200 administrations of nitrous oxide-oxygen. The patient was dead six minutes after entering the operating room. He also reports another case in which the patient

was resuscitated with great difficulty. Dr. Roy McClure, now of the Johns Hopkins, reports to me two deaths which occurred while he was connected with the New York Hospital. These occurred in the service of Dr. Frank Hartley, and took place while gas was being given as a preliminary to ether. Dr. McClure was resident surgeon at this time, and is entirely familiar with the facts.

From inquiry as to nitrous oxide-oxygen at the Mayo clinic, I find that this anesthetic was used in about 1,400 cases as a preliminary to ether. I can learn of no mortality, but the result was not satisfactory and it was dropped. Miss Henderson, the anesthetist, under date of January 16, 1915, wrote that on the day before Dr. E. J. Burch of Carthage, Mo., reported to her a case which he had lost under nitrous oxide-oxygen. The anesthesia had been a brief one for a rectal examination. The examination was completed and the surgeon left the room, but was called back hurriedly and found the patient dead. She says of the nitrous oxide-oxygen anesthesia: "We have investigated its merits at various times, but the surgeons have not seen fit to make any change from 'drop ether,' which has been used here for many years." A personal communication from Dr. Burch affirms this report.

In conversation recently with two of the best known surgeons of Cleveland, Drs. Bunts and Skeel, I found that no thorough investigation of nitrous oxide-oxygen deaths had ever been made in that city; numerous instances were known, but the details had never been published. Both of these surgeons used ether by preference, but because of the newspaper prominence given nitrous oxide-oxygen they were obliged in some cases to yield to the request of their patients and use that anesthetic.

Gwathmey[2] (p. 109) reports three fatalities out of 2,500 cases. In the first case death occurred suddenly before operation was commenced. In the second it also occurred suddenly, but the operation had begun and the anesthesia up to that point had been normal. In the third case the pulse became very rapid, and at the close of the operation went up very rapidly. Color became cyanotic and could not be cleared up with oxygen, the breathing became weaker and weaker and finally ceased. Because at the autopsy an enlarged thymus was found, with hypertrophy of the lymphatic tissues in general, the pathologist gave status lymphaticus as the cause of death.

Recently (December 5, 1915) Dr. T. G. McCormick, now of Portsmouth, Ohio, formerly of Detroit, told me that they had had either seven or eight deaths at Grace Hospital, Detroit. He was resident physician there during that time, and one of the deaths occurred while he was giving the anesthetic. He could give no particulars of any of the other cases, but his own patient died suddenly and without any warning.

The following is the Columbus death list for nitrous oxide-oxygen:

1. The first death in Columbus from nitrous oxide alone occurred some years ago at the Dental Clinic of the Ohio Medical University. The gas was given for the extraction of teeth, and the patient died suddenly and without any warning. Efforts at resuscitation were made as usual, but were unavailing. My authority is Dr. A. O. Ross, then dean of the dental department.

2. Probably the first death in this city from nitrous oxide-oxygen took place at Mt. Carmel Hospital, the anesthetist being a physician who was considered an expert, and who is among the best known anesthetists of New York City. The patient, according to the anesthetist's statement to me, died suddenly in the midst of a somewhat prolonged abdominal operation.

3. Dr. G. W. Mosby of Columbus reports to me that he had a patient die from nitrous oxide-oxygen, also at Mt. Carmel Hospital, the anesthetic in that case being given by Dr. Jones. The operation was for pelvic infection. The operation, he says, had lasted about forty-five minutes, and was proceeding satisfactorily apparently, when the patient suddenly died. He unhesitatingly attributes the death to the anesthetic.

4. Dr. R. B. Drury reports that last year at the St. Clair Hospital a woman was being put under nitrous oxide-oxygen anesthesia by Dr. Jones, for the removal of a fibroid by the late Dr. Leach, whom Dr. Drury was assisting. Just at the beginning of the incision the woman suddenly expired without the slightest warning.

5. Dr. Drury also reports a death from nitrous oxide-oxygen in a man aged 65, whom he operated upon at Washington Courthouse. A year before the same patient had had a suprapubic prostatectomy under ether by the late Dr. Leach, and went through the operation nicely. Further trouble coming on, Dr. Drury decided to operate through the perineum. Nitrous oxide-oxygen was given by Dr. Rice. In the midst of the operation, which had been going on all right, the patient suddenly expired.

6. Dr. George Williams reports that at the St. Clair Hospital he gave nitrous oxide-oxygen for a hysterectomy for fibroid tumor, about one year ago. The patient went through the operation very satisfactorily, and the surgeon was about to close the incision when the patient suddenly died without any warning whatever; had been doing well up to that moment.

7. Dr. G. L. Saunders tells me that about four years ago, while waiting for a patient of his own to be operated upon at Mt. Carmel, he witnessed an operation on a colored woman, probably 35 years of age, who was suffering from a small fibroid. Nitrous oxide-oxygen was being given, and just as the abdomen was being opened, and before any work on the inside had commenced, the patient suddenly died without any warning. All efforts at resuscitation failed. Dr. Saunders was a stranger in the city, and did not know the anesthetist.

8. Dr. Goodman reports that on March 13, 1913, he opened through the vagina a cul-de-sac abscess. The case was a puerperal one of two weeks' standing. Nitrous oxide-oxygen anesthesia was given by Dr. Rice. The opening of the abscess took but a moment, but the patient suddenly died on the table.

9. Dr. Goodman reports the case of a young woman, mother of a child two years of age, upon whom he operated for the removal of fibroids. The husband, against the wishes of the surgeon, insisted on the use of nitrous oxide-oxygen. A supravaginal hysterectomy was made in the usual way, the operation being exceedingly easy. There were no adhesions, and the operation took about twenty minutes. The patient had taken the anesthetic beautifully, breathing quietly, and with good color. As the last stitch was being inserted the patient ceased to breathe and the heart stopped. Dr. Rice was giving the anesthetic. Dr. Goodman at once opened the abdomen, massaged the heart through the diaphragm, giving deep injections into the heart of adrenalin, besides using oxygen and artificial respiration, dilating the sphincter ani, etc., but the patient was dead.

10. This patient was a woman operated upon by Dr. Howell for abdominal tumor. She had had one kidney removed some time before, and was known to be suffering from nephritis. Nitrous oxide-oxygen was used. After the operation there was bloody urine, then suppression of urine, then death from uremia. (Had this suppression of urine occurred under ether, the death would undoubtedly have been attributed to the ether; by a parity of reasoning it should be attributed to the nitrous oxide-oxygen, though it is possible that the anesthetic had nothing to do with the death.)

11. Dr. J. M. Thomas reports that about two years ago Dr. Howell operated upon a patient of his, 22 years of age, for chronic appendicitis; had suffered from infantile paralysis, and had some functional heart trouble. Dr. Rice gave the anesthetic. The operation was completed, and Dr. Howell had left the room, when suddenly the patient went bad, and apparently died on the table. Dr. Fletcher and several others were present. Artificial respiration was kept up, he says, for justy sixty minutes, when she breathed herself for about ten minutes. The abdomen had been reopened by Dr. Howell, the heart massaged, and adrenalin injected into the heart substance. After breathing for ten minutes respiration stopped and further resuscitation was impossible. He is positive that the death was due to nitrous oxide-oxygen.

12. Mrs. McC., aged 37, had a simple abdominal hysterectomy October 28, 1914. In spite of my own protests and those of her attending physician, she insisted on taking nitrous oxide-oxygen. Dr. Rice administered the anesthetic, which she took beautifully, but just at the completion of the abdominal work, without the slightest warning, the heart's action suddenly ceased and the patient was dead. The heart was at once massaged through the open abdomen, and all the usual measures for resuscitation instituted, but in vain.

13. Mr. B. of Degraff, aged 62, was operated upon February 26, 1914; had been having severe attacks of pain in the region of the gall bladder, and his physicians thought that he had passed gall stones. He had had some bronchorrhea for several years; no kidney trouble. Because of the history and local conditions a gall-bladder operation was advised, and because of the bronchorrhea I advised nitrous oxide-oxygen. There was hypertrophy of the heart, but no valvular lesion could be detected. Pulse regular, and of good volume. The diagnosis was a matter of doubt, but malignancy could not be positively excluded. An incision was made over the gall bladder, which was found distended. At this time the patient was reported by Dr. Rice to be doing badly, and an instant examination showed a pulseless aorta. The heart was at once massaged through the diaphragm, artificial respiration kept up, etc., but all efforts were without avail. Autopsy showed an enlarged heart, but no dilatation.

14. Mr. L., aged 62, was brought to the hospital May 14, 1912, with a diagnosis of peritonitis from appendicitis. His condition when he reached the hospital was bad, as he had got chilled on the train coming up. In the course of an hour this condition improved, so that he had a good color, and a good heart's action. His condition was such as to indicate extensive infection, and I planned to make a quick incision and put in a drain. For this purpose I thought nitrous oxide-oxygen safer than ether. He took it nicely, but just as the incision was made he died suddenly. After death was determined the incision was extended somewhat, and it was then found that there had been a plugging of the superior mesenteric artery, all the intestines supplied by the artery being black and devitalized. Of course, death would have occurred within a few days, so that the anesthetic death was of no special importance. Within a few months of this time, however, I had two similar cases, one in a young woman of about 30, the other in a man of about 60. Ether was given in both cases, the abdomen opened, the condition determined, and the abdomen at once closed. Both survived the exploration by a day or two.

The above list shows that we have had twelve, or more properly perhaps thirteen, deaths from nitrous oxide-oxygen when given for major operations. Careful investigation seems to show that there have been not to exceed twelve or thirteen hundred administrations of this anesthetic for major operations, in Columbus, so that the death rate has been practically 1 per cent.

Without persistent effort on my part, few of the nitrous oxide-oxygen deaths in Columbus would have been unearthed. I have made no canvass of the situation in other cities of the State, but incidentally know of several deaths in Cincinnati, Cleveland, Toledo, and Akron. In one of the Cincinnati cases the anesthetist was a specialist of twenty years' experience, who had spent two weeks at Lakeside to familiarize himself with the details of the nitrous oxide-oxygen anesthesia. He had administered the combination successfully in a number of cases, but in this particular case (nephrotomy for stone) he had objected to the giving of the gas as he preferred ether, but the surgeon insisted and he complied. The anesthesia went off beautifully, the operation had lasted about thirty minutes, and was just about completed when the patient suddenly died. (Personal communication from the anesthetist, Dr. Leroy S. Colter.)

Under date of June 1, 1916, in response to a letter of inquiry following a newspaper announcement, Dr. H. H. Wiggers of Cincinnati writes me that the death of a married woman in his practice "occurred suddenly, without any warning. There was simply a cessation of the heart beat. We cannot account for the death." No details of operation given, but the anesthetist was a specialist, with an experience of about eleven hundred cases of nitrous oxide-oxygen anesthesia.

Gwathmey, concerning whose skill and experience there can be no doubt, under date of November 6, 1915, gives me a personal report of a death which he had had a few days before, and which he expects to report at an early date. This death under nitrous oxide-oxygen, he says, "was absolutely uncalled for, and has changed my ideas of the safety of nitrous oxide-oxygen entirely. . . . I believe if I had given him ether the man would have been alive today."

In commenting on autopsy No. 3394, Dr. Hugh Cabot, of the Massachusetts General Hospital ("Case Reports" received January 16, 1916), says in regard to a death from nitrous oxide-oxygen, that "during the operation the anesthetist remarked that the breathing was slow, but the color of the skin normal. The color of the blood was at no time observed to be unusual. At the point last described the anesthetist observed that the respiration had stopped. Artificial respiration was started and kept up for forty minutes steadily, with the liberal use of oxygen. . . . This was an anesthetic death due to gas and oxygen anesthesia." The anesthetist in this case was Dr. Freeman Allen, chief

of the department of anesthesia, and consulting anethetist to the Massachusetts General Hospital and Children's Hospital.

Ochsner[5] says that he made a careful test with one hundred successive cases of nitrous oxide anesthesia, compared with a similar number of ether anesthesias by the drop method. He says he "found no difference in the course of the anesthesia, nor in the comfort of the patient, but there was a little more bronchial irritation following operation when nitrous oxide-oxygen gas had been used." (Absence of bronchial irritation is one of the strong claims made by those who advise this anesthetic.) The method, he says, he found cumbersome, and, therefore, permanently abandoned it. The only special value that he attributed to it is a "slight advertising value which the method undoubtedly possesses." He then speaks of the addition of oxygen to the nitrous oxide gas, and claims for it the same advertising value as for the other, but "possibly to a somewhat greater degree." He then speaks of some of the disadvantages which it has, and finally concludes as follows: "For some time to come there will be a certain amount of advertising advantage, but as soon as this has been dissipated through the fact that every one will be prepared to administer this form of anesthesia, its drawbacks must become apparent as compared with its advantages."

In Columbus nitrous oxide-oxygen deaths have occurred at the hands of three administrators, all of whom are looked upon by their friends as thoroughly competent specialists. Deaths have occurred to each in frequency just about in proportion to the number of administrations for major operations. Dr. Rice has lost the largest number, but has undoubtedly had more administrations in major work. Dr. Howell, who has made a personal study of nitrous oxide-oxygen anesthesia, and has watched many such administrations at Lakeside, Cleveland, and who has until recently used nitrous oxide-oxygen almost exclusively, tells me that he regards Dr. Rice as the most skillful nitrous oxide-oxygen anesthetist in the State. The anesthetist who had but one death had given this anesthesia in about fifty cases.

We are told by many that while deaths on the table are exceedingly rare from ether, many deaths occur later from pneumonia, which should be charged up to ether. Those who make these statements should certainly read Rovsing[1] (p. 85), who considers this matter briefly but very forcibly: "It is astonishing, moreover, that the misconception that ether has a harmful influence on the pulmonary passages still exists, because in reality the correctness of this view has long since been refuted, both clinically and experimentally. From a clinical point of view it was Mikulicz's report in 1898, which drove the nail home. Mikulicz, on account of the somewhat frequent occurrence of postoperative pneumonia, had deserted ether and taken up chloroform, in the belief that the pneumonia was due to the irritating effect of the ether. To his surprise, however, it appeared that the cases of chloroform narcosis were followed by a still greater percentage of postoperative pneumonia. He, therefore, decided to give up narcosis by inhalation entirely, and thereafter employed local anesthesia in all operations, even the major ones. But, to his yet greater surprise, the result was that the lung complications, far from decreasing, increased to a considerable extent: with 114 laparotomies he had no less than twenty-seven lung complications. Naturally, this experience overthrew the old conception that postoperative cases of pneumonia were 'narcosis pneumonia.' One curious fact should long ago have aroused the surgeon's suspicions; namely, that almost every 'narcosis pneumonia' manifested itself after laparotomy, while it is extremely rare to find pneumonia following operations on the extremities, thorax, and head. To what was this strange occurrence due? Surely, in the main, to two circumstances: (1) That peritoneal infection is conveyed to the lungs partly by way of the lymph vessels and venous blood, and partly by embolism, and (2) that a patient with a laparotomy wound dares not cough or breathe freely, inasmuch as this involves pain in the wound. If, therefore, the patient is already suffering from bronchitis, or if an infection of the lungs sets in, the development of pneumonia is greatly favored by the deficiency in expectoration and lung ventilation.

"It has been proved experimentally with animals —and I myself have substantiated the fact by experiments—that ether does, indeed, occasion increased salivation in the salivary glands of the mouth, but that the air passages—larynx, trachea, and bronchi—are not irritated at all, even when the animals are killed by administering ether through a tracheotomy tube until they are dead. Therefore, the only way in which ether narcosis *per se* can cause pneumonia is by aspiration of accumulated saliva in the throat. This, however, is always due to some technical error in the narcosis, for saliva should not be allowed to accumulate in the throat to any extent. . . . If, therefore, it is proved that the ether fumes do not in any way irritate the main air passages, one should admit that the other assertion must also be wrong. I mean the assertion that ether is contraindicated in patients suffering from lung disease: emphysema, bronchitis, bronchiectasis, abscess of the lung, etc."

I have had ether administered in very many thousands of cases; years ago by use of the old-fashioned cone, then the Allis inhaler, and now for a number of years by some form of the drop method. I have never had a death on the table from its administration. I cannot recall a single death from postoperative pneumonia. I have had two or perhaps three deaths from suppression of the urine. It is possible, perhaps probable, that this suppression was the result of the action of the ether on the kidneys, and yet we all know that deaths from suppression occur in cases in which no anesthetic whatever has been given, and earlier in this paper I have referred to one death in which suppression of the urine followed the administration of nitrous oxide-oxygen.

Nitrous oxide-oxygen has a field of usefulness to which it should be strictly limited. It can be used for very brief operations, as it has been for many years in the extraction of teeth. It is also probably the safest anesthetic to use, as suggested by Ochsner, in cases of acute pulmonary congestion, or of acute nephritis. With these exceptions, which make its field a very limited one, nitrous oxide-oxygen should be looked upon as the most dangerous anesthetic that can be used, even in the hands of the most experienced.

PELLAGRA—A CRITICAL STUDY.

By JOHN AULDE, M.D.,

PHILADELPHIA, PA.

Introduction.—The object of the present article is to make a critical survey of the dietary defects responsible for the appearance of pellagra, a mysterious malady which now prevails throughout the Southern states. Such a study is made possible through the information contained in two publications[1,2] recently issued by the United States Public Health Service. Like scurvy and beriberi, attacks of pellagra have generally been regarded with suspicion, because of their insidious, seasonal development, with apparent recovery and persistent recurrence. Fortunately, the data at hand is of such a character that we can bring to bear upon this disorder the modern searchlight of scientific inquiry—which gives promise of arousing widespread interest. This favorable outlook is not dependent upon relief from pellagra alone, nor is it limited to scurvy and beriberi, these disorders being rare in this country. On the contrary, the principles underlying the successful treatment of these diseases by diet alone are universally applicable in all diseases, acute, subacute and chronic, functional and organic, infectious and non-infectious, because in every instance we have to contend with the effects, direct and indirect, immediate and remote, arising from dietary deficiency, evidence, complete and in detail, being supplied in the accompanying tabulations.

Historical References.—In view of the very unsatisfactory results attending the investigations of many learned men, physicians, chemists, and bacteriologists, for the past two hundred years, it would not be profitable to review the long campaign. The recent history of attempts to conquer the malady can be briefly stated. By way of explanation, it should be mentioned that there has always been two sides engaged in the controversy—one party claimed that it resulted from some occult dietary fault, corn meal being blamed, while the other party insisted it must be due to an infection.

Several years ago a commission was organized in London, three experts (physicians) were employed, but in their latest published report they say, "their efforts to discover the essential, pellagra-producing food, or the essential, pellagra-preventing food have not been crowned with success." Substantially the same conclusion faces the Public Health Service, in the attempt to demonstrate the infectious organism, this bacteriological work having been under way now for several years in different places throughout the South. In this connection it should be stated that no claim is set up that the pellagrin is free from bacterial infection—far from it; but there is no specific microorganism by which the disorder may be transferred to man or animals, as is the case with diphtheria, tuberculosis, and other infectious diseases.

Two years ago an entirely new theory was launched, which assumes that this disorder must be due to the "over-milling" of corn, by which process of refinement certain vital elements essential to maintain the activity of the various digestive functions are removed, such, for example, as the polishing of rice.

The United States Public Health Service has recently issued an interesting report on vitamines,[3] showing their efficiency in preventing and curing polyneuritis in pigeons fed on polished rice. In this instance, the vitamine was obtained from brewer's yeast, the source of yeast nuclein, first advocated by Vaughan in 1893. While the evidence in favor of yeast vitamine is decidedly favorable, it remains to be seen whether yeast nuclein will produce equally satisfactory results. Thus, "A pigeon kept on polished rice without the yeast filtrate begins to lose weight usually within the first five days, and dies with the typical paralysis of polyneuritis within about twenty days. If 1 c.c. of the yeast filtrate is given to completely paralyzed pigeons, a relief of the paralysis will occur within an hour, and to all outward appearances the pigeon will be restored to a normal condition within twelve hours." The author also refers to the experimental work of Chamberlin and Vedder (1911), who showed "that the neuritis-preventing substance of extracts of rice polishing is removed by filtering through bone-black."

In this connection it should be added that the polyneuritis and paralysis, as occurring in pigeons from polished rice, are a counterpart of the symptoms witnessed in beriberi. In addition, the writer has frequently traced neuritis to excessive rice eating, but has invariably relieved the condition by reorganizing the dietary together with administration of lime salts.

Another important item relates to the laboratory method of concentrating the yeast filtrate for convenience in administration to humans—by using aluminum silicate to secure adsorption. The daily dose of this latter substance for adults amounts to 5 grams (75 grains), and since Dr. Seidell suggests the employment of vitamines for pellagra, we must bear in mind that both silica and aluminum have been held responsible for this disease.

Preceding the "vitamine" theory several specious theories have been advanced within the past few years, one of which deserves attention, viz., that *silica in the food* eaten and water drunk can produce the disease. The plausibility of this conception seemed at first a deduction fully warranted, when it was shown that guinea-pigs, rabbits, dogs, and monkeys fed upon silica developed the characteristic symptoms recognized as belonging to pellagra. The fallacy of this theory was shown by the writer[4] in a short article in which it was indicated how silica became a factor in experimental work. Thus, pellagra is a disorder characterized by a diminished alkalinity of the blood (acid excess), and as a result of this chemical deviation there follows depletion of the lime salts, magnesium salts taking their place. By or through this substitution there is an excess of magnesium salts in the tissues—then the addition of silica, which has an affinity for magnesium, gives rise to a new combination, magnesium silicate. Like sodium silicate, magnesium silicate shows a tendency to harden when it is cooled, and that accounts for the various "rheumatic" affections which involve principally the smaller joints. The sponsor for silica, Alesendrini, an Italian, had previously written a book to prove that pellagra was an infectious disease, but this he renounced when he took up silica, a marked illustration of the uncertainties attending medical investigations.

Along about this period came another specious theory, namely, that pellagra was caused by *the presence of aluminum* in the food—and that the injurious effects arising therefrom might be counteracted by adding fresh animal meat to the dietary, an amusing and ridiculous suggestion to the confirmed vegetarian. The fallacy of this

theory will be appreciated by recalling the objections offered to silica as the causative factor—the latter has an affinity for magnesium and aluminum has a double affinity for silica. This accounts for the pellagra symptoms produced by either silica or aluminum in laboratory work, when employed experimentally in animals, usually in massive doses, to study the effects, physical and physiological. Such experiments in this instance have no practical bearing upon the case, since neither silica nor aluminum are taken into the system with our daily food or otherwise in such quantities as would or could produce the characteristic symptoms of the disease.

About a year ago, a thoughtful and industrious Italian, Dr. A. Cencelli, published an incisive paper[5] giving an account of his efforts to counteract the injurious effects of silica in the drinking water. Small pieces of lime were placed in the pipes and reservoirs, and the treatment was applied not only to animals in which the disease had been induced, but also to human beings who had been suffering from pellagra for longer or shorter periods of time, and "the results were in the highest degree satisfactory. Persons who had been ill for a long time immediately improved and were cured in a relatively short space of time, without any change having been made in their mode of life, surroundings or diet."

Evidently, Dr. Cencelli had overlooked my contribution[6] published more than six years ago, from which the following extract will show my trend of thought at that time: "In the opinion of the writer, the underlying, causative factor is to be found in magnesium infiltration, a pathological condition in which there is a depletion of the lime content of the nuclear proteid, being the counterpart of that which occurs in plant life when magnesium salts in excess cause destruction and death of the protoplasm, since magnesium acts as an insulator, impeding the uninterrupted transmission of nerve impulses."

At the time this paper was written serious complaints had been lodged against all corn products employed throughout the South, and it was shown beyond question that the letting of contracts to the lowest bidder had deluged that section of the country with deteriorated grain, the principal sufferers being the inmates of asylums. Indeed, in several instances, charges were brought against the managers for negligence on the part of attendants—it was assumed that the hands and feet of the victims had been scalded, the skin eruptions being so marked as a result of the disease.

In this connection another quotation may be permitted, as follows: "A significant factor in this connection relates to the normal acidity of corn meal; that is to say, when corn meal of good quality is submitted to the usual chemical tests it shows a relative acidity varying from 13 to 25 per cent. When corn meal of an inferior quality—due to decomposition from various causes—is tested, the acidity is found notably increased, in some cases running as high as 95 per cent."

The questions relating to magnesium infiltration and acidity will be better understood from the analysis of the dietary studies, and need not be taken up at this point, but one more reference should not be omitted. Fifty years ago, a Frenchman, Roussel,[7] published a book, from which the following extracts are copied: "Without dietetic measures, *all remedies fail.* . . . When drugs and good food are simultaneously employed it is to the latter that the curative action belongs; the former simply exercises an adjuvant action and is without proved efficacy, except against secondary changes or accidental complications."

The Public Health Service Reports.—These reports are skeletal in character, and yet they furnish a substantial basis upon which to erect the superstructure—they merely supply the daily bill of fare or menu without any details as the nutrient values of the various food materials. Upon the assumed theory that pellagra is due to a dietary deficiency, lack of protein with a superabundance of starchy food-stuffs, the experimental work was taken up with the understanding that it should be continued for a period of two years. The results proved so favorable that a report was made at the end of the first year, and it is this data which we have under consideration. There were really three operations, one embracing two orphanages situated near Jackson, Miss., another located in the grounds of the State penitentiary, with eleven volunteers, while the third was confined to two wards of the Georgia State Sanitarium, an asylum for the insane, where 72 insane women (36 white and 36 colored), all pellagrins, were placed under treatment. As a result of care in the diet there was but one case developed in the orphanages, and all who had the disorder at time of beginning made complete recovery. Altogether, there were more than two hundred cases under observation—and a point worth noting in this connection is that the history of the disease in both institutions showed that it had been confined exclusively to children between the ages of six and twelve years. This peculiarity is readily susceptible of explanation—up to six years of age the children were provided with milk three times a day, but none allowed after that age. This will partly anticipate the value of diet, more fully elaborated in the analysis. The "Pellagra Squad" was confined to criminals who volunteered to take the diet which was supposed to produce the disease, on condition that they receive a pardon from the Governor of the State.

Only two of the operations are included in this paper, the dietary of the orphanages not being available for tabulation—and the accompanying tables are self-explanatory. Thus, to produce the disease a liberal supply of starchy food-stuffs were given, no meats being allowed; to prevent and cure the disease a dietary was provided which included a half pound of beef daily, along with legumes and little of the starchy food. Each dietary study is preceded by the data furnished by the Public Health Service, the computations being worked out by the writer—to show as a whole and in detail the nutrient value of the dietary selected—and special attention should be directed to the importance of the mineral constituents, a computation not usually included in dietary studies.

Dietary Studies.—The object of a dietary study is to determine with mathematical accuracy the nutrient value of the various foods eaten from day to day, or month to month. Sufficient evidence has accumulated to enable us to determine the minimum demands of the system for rebuilding materials and for fuel, or heat-producing materials, so that it is comparatively easy to make computations for different persons employed at different tasks—and allowance must also be made for the season of the year, less fuel material being required in hot weather than during winter. The minimum demand is based upon the needed repairs, sixty grams (about two ounces) of protein being required for this alone. Starting with this, the demand for

carbohydrate is estimated at four times the amount, while one-fifth of the whole (about two and one half ounces) should be fat. Food materials taken in excess of the above amount (about twelve and one-half ounces), should be in like proportion to maintain good health. Slight variations may be made from time to time, but when long continued the evidences of debility become well marked and may be readily detected by the skilfull physician.

These nutrient elements, protein, fat and carbohydrates all produce heat, while at the same time serving other purposes; thus, the protein of meat or potato produces the same amount, 4.1 per cent. per gram, but the fat eaten produces more than twice as much, 9.3 per cent. per gram, a gram weighing a little over 15 grains, or one-fourth of a teaspoonful. Meats contain both protein and fat, but no carbohydrate, while legumes (potatoes, etc.), and cereals contain all of the elements—in varying proportions.

The computations to determine the amounts of protein, fat and carbohydrate have been made from Atwater's tables[8] which are generally accepted as authoritative, while the percentages of calcium and magnesium are taken from my book,[9] the data having been compiled from the monograph by Sherman, Mettler, and Sinclair,[10] Department of Chemistry, Columbia University, New York.

The amounts of the various food materials are given in the table, together with the computations, and with the exception of the rates for brown gravy are approximately correct. As there was no heading for brown gravy in Atwater's tables, meat stew was substituted as being nearest in point of protein, fat and carbohydrate and the percentages of calcium and magnesium have been omitted, but this omission will not affect the general results. The probability is that brown gravy would affect the caloric value, since the fat content would be greater, but it would not involve the mineral constituents. In addition it should be mentioned that fried mush is rated as corn bread.

Table I—Dietary Study—Experimental Pellagra (Camp Study).

Food Materials	Weight, Lbs.	Protein, Lbs.	Fat, Lbs.	Carbohydrate, Lbs.	Calories	Calcium Oxide, Grains	Magnesium Oxide, Grains
Biscuits	41 81	3 637	1 087	23 120	54,357	61 460	55 580
Corn bread	24 56	1 940	1 154	11 371	29,628	15 472	226 870
Grits (hominy)	27 06	.595	054	4 816	10,076	17 047	250 033
Rice	24 25	679	024	5 917	12,370	20 370	101 850
Fried mush	33 87	2 675	1 591	15 681	40,856	21 338	312 958

As a result of the "*Camp Dietary*" no less than six of the inmates developed symptoms pertaining to pellagra. At first, there was intestinal irritation (diarrhea), and this was accompanied by lack of appetite, loss of strength and weight. Later, mild nervous symptoms appeared, but it was not until five months after beginning treatment that the "typical" skin eruptions developed.

The "*Asylum Dietary*" is thus described in the report: "A cup of sweet milk, about 7 ounces, is furnished each patient for breakfast and one of buttermilk for both dinner and supper. About half a pound of fresh beef and two to two and one-half ounces of dried field peas or dried beans enter into the daily ration. Oatmeal has almost entirely replaced grits as the breakfast cereal; syrup has been entirely excluded. Corn products, though greatly reduced, have not been entirely eliminated."

The menu for Tuesday, selected for this study, is as follows:

Breakfast.—Grits, sweet milk, sugar, broiled steak, hot rolls, biscuits, coffee.

Dinner.—Beef stew, potatoes, rice, bread, buttermilk.

Supper.—Baked beans, light bread, coffee, sugar, buttermilk.

As the exact amounts of oatmeal, sugar, bread, potatoes and rice are not given, it was assumed that they had one portion, the weight of each being added in the proper column. Thus, the total amount of food eaten for the day is 51.5 oz., or 3.21 lb., two-fifths of which is milk and buttermilk.

Table No. III, "Comparison of Dietary Values," has been added for the purpose of showing the "one-sided" character of the dietary selected instead of a "balanced ration"—it shows at a glance just how the two dietaries could be readjusted to meet the normal demands of the system.

Analysis of the Tabulations.—By comparison and contrast we may arrive at definite conclusions, at least from a mathematical viewpoint, but there are physiological and chemical questions to be brought into consideration. For example, it is easy to make the calculation and find that each dietary carries

about two pounds a day more than is utilized; that the protein content of the "Camp Dietary" is 30 per cent. above the minimum, while the protein content of the "Asylum Dietary" is 70 per cent. above the minimum; that both dietaries were lacking in the fat content of a "balanced ration"; that the "Camp Dietary" had a surplus of carbohydrate of about 200 grams while the "Asylum Dietary" had a deficiency of like amount. Most important, however, is the notable discrepancy in the mineral content—the "Camp Dietary" contains about two and one-half times as much magnesium as lime, while the lime content of the "Asylum Dietary" is one and one-half times the magnesium content. Now comes the question as to which has the greater influence, the discrepancy in the fat and carbohydrate, or the reversal in the proportions of the calcium and magnesium? Vegetarians live a normal life without fat, animal fat, so that question is settled. Hard working men will consume food which produces twice as many heat units (calories), as these men in the camp, who worked four and a half days per week, enjoy life and apparently suffer no bad effects from the increased intake of carbohydrates. Again, the absence of carbohydrate from the dietary is not at all serious, as shown by the freedom of the asylum inmates from recurrences of the disease, several of whom had experienced two or more attacks. Further, there were more than 72 patients under treatment at the beginning of the course, but some of them so far recovered under the treatment that they were permitted to go to their homes. It is doubtful if the excess of protein in the "Asylum Dietary" could have exercised such a marked change, since the "Camp Dietary" contained 30 per cent. above the minimum requirement.

Table III—Comparison of Dietary Values.

	Actual Ration				"Balanced Ration"			
	Protein, Grams	Fat, Grams	Carbohydrate, Grams	Calories	Protein, Grams	Fat, Grams	Carbohydrate, Grams	Calories
Camp dietary	78	36	515	2766	78	97	312	2501
Asylum dietary	103	84	232	2154	103	128	412	3301

This leaves for consideration the function of mineral constituents, but that harks back to the protein element in the dietary. It is not an accumulation of fat which gives a man mental ability and physical strength; nor can either be claimed for carbohydrate. Hence, the necessity for interrogating nature.

In the "Asylum Dietary" nearly 16 of the 20 grains of lime were derived from the milk and buttermilk, while the magnesium came chiefly from oatmeal, rice and baked beans—in fact, when a child gets 7 ounces of sweet milk and 6 ounces of oatmeal, the mineral balance is in favor of lime by more than one grain. But a child twelve months of age will take a quart of milk a day and thrive on it—by which he gets about 24 grains of lime daily.

Now, let us examine the "Camp Dietary"—the lime was derived principally from biscuits, sweet potatoes, collards and cane syrup, while the magnesium content came from corn products almost exclusively—with the rice content, it make up nine-tenths of the whole. Had it not been for the cane syrup the "pellagra symptoms" would have appeared much earlier and shown greater severity. Then, if we add to this a decomposed or deteriorated corn preparation with an excessive relative acidity, we have a fairly complete picture of the conditions which precipitated this malady in the first place and kept it alive for two centuries.

In the usual dietary of the ordinary home in this country, Langworthy has calculated that the average intake of calcium ranges from 10.5 to 15 grains daily, the magnesium content being estimated at half this amount—and this apparently accounts for the prevention of the recurrence of the disease in the two wards of the Georgia State Sanitarium.

Deductions from the Evidence.—The general reader must concede that we have a pretty good case, but the evidence is not all in. For example, as soon as the camp subjects began to suffer from intestinal irritation, an examination of the blood would have shown that they were suffering from calcium depletion incident to the acid excess; that the normal alkalinity of the blood was diminished, interfering with its oxygen-carrying capacity; that the heart action was enfeebled as a result of the chemical deviation; and finally, that nerve conduction was impaired—in consequence of the calcium depletion and in the coincident substitution of magnesium. It is precisely on the same principle that a farmer would not permit the use of lime on his land where it contained a large percentage of magnesium, because he knows that such a combination would be fatal to his crops.

The essential factor in the production of pellagra, scurvy and beriberi, and in fact, all chronic diseases, is the mineral deficiency in the protein molecule. The protoplasmic cell is the unity of which the body is made up, just as the bricks are the unit in a solid brick wall, except that these cells are living organisms, possessing all the characteristics and properties of life, nutrition (absorption), excretion, motility, reproduction and response to stimuli, and to this should be added the psychic. These cells are made up of the food taken into the system; they are composed of molecules—of fat, carbohydrate and protein molecules, and the functional activity and physical energies of the protoplasm are dependent upon the proper distribution of the mineral salts, not in the fat and carbohydrate molecules, but in the protein molecules. It is the protein molecule which enables the protoplasm to perform its special or specific functions in muscular tissue, kidney structure, in the liver, the lungs, the brain, the reproductive organs, and finally, maintains correlation with all the organs through the medium of the nervous system. When illness supervenes, there is at once an acidity, or diminished alkalinity of the blood, and lime being a stronger base than the others, this substance combines with the acid and is eliminated. Thus, a person living on crackers and water for three days will lose more lime than the intake—and he will begin to lose it during the first day of the experiment, all of which goes to confirm my contention that calcium depletion is responsible for pellagra.

Bacterial Infection.—This claim is further confirmed by a study of bacterial infection. Under normal conditions it is the protein molecule which enables us to ward off disease, by maintaining an antiseptic condition of the blood; by promoting or favoring the production of bacteriolysins, substances which dissolve the bacteria; by the production of poisons (bactericides), which kill the invading hosts of bacteria; by augmenting and

strengthening the functional activity and physical energies of the phagocytes, which surround and digest the bacteria when found in the blood stream and in the tissues, this peculiar feature of defense being regulated by chemotaxis. In none of the conditions can we depend upon nature when the blood and lymph and tissues are surcharged with magnesium salts, because bacteriologists have shown time and again that when the blood is charged, surcharged, with a considerable percentage of magnesium sulphate (Epsom salts), it loses its bactericidal properties.

On the other hand, the presence of magnesium salts in excess seems to favor the growth and multiplication of bacteria, the constitution of which is substantially the same as the protoplasm, simply because magnesium salts in excess are debilitating —as in the case when they are substituted for the calcium salts in the body tissues, their function is impaired. Normal nucleoproteins are converted into magnesium nucleoproteins and these latter lack the property of imbibition (absorption), and this explains why the wise farmer refuses to put lime salts surcharged with magnesium on the soil; he knows that the tiny rootlets will shrivel up, turn black and die and that his crop will be a failure—and such is substantially the picture we see when the searchlight of scientific inquiry is thrown on the disease known as pellagra.

THE DRUG HABIT.

By FRANK A. McGUIRE, M.D.,
AND
PERRY M. LICHTENSTEIN, M.D.,
NEW YORK,
PHYSICIANS TO THE CITY PRISON (TOMBS).

So much has been recently written on this subject, and so many different views of it have been taken by the different writers, that it would seem that we owe an apology for writing the present article.

We are, however, convinced that this subject as herein discussed will be of interest to all who read its contents. As physicians to the City Prison (Tombs), Manhattan, it has been our opportunity to come in contact with and treat approximately twelve thousand cases within the last twelve years. This is a conservative estimate. We have observed and studied people so addicted, and we have instituted a definite treatment, which has proved effective. The drugs most often used are opium and its derivatives and cocaine.

Opium is the concrete milky exudation obtained in Asia Minor from the unripe capsules of *papaver somniferum*, by incision and spontaneous evaporation. It is usually put on the market in subglobular, flattened, irregular cakes, chestnut brown or somewhat darker in color. The mass is plastic, but on keeping a harder external crust is formed. The cakes weigh from 4 ounces to 2 pounds. Opium has a heavy, sweetish odor and a disagreeable bitter taste. At present the use of this drug by addicts is restricted, owing to the increase in price. This fact has resulted in causing opium users to resort to heroin, the latter being more readily procured. Opium smokers may be divided into two classes: (1) Pleasure smokers; (2) Fiends. The pleasure smokers are usually found among the well-to-do and business men, actors and actresses, and the sporting element. They smoke only occasionally and are not confirmed addicts. On the other hand, the fiend is one who practically lives in the opium dens. Such people lose all ambition and simply smoke and sleep.

Pleasure smokers usually are possessed of most elaborate layouts. They have costly jeweled pipes and dens fitted accordingly. The fiend usually craves to smoke in company and is not very particular in choosing his company. Usually men and women smoke together. A mattress is placed on the floor. The man who prepares the opium lies down, the second smoker places his head upon the abdomen of the first; the third will assume a similar position, and so on with the others, forming a circle. The man who prepares the pill then takes the yen hok, which is shaped somewhat like a probe, having one pointed end. He places a small piece of opium on the point of the yen hok and heats it over a tiny flame of a small lamp, used for that particular purpose. The lamp is filled with an oil which will not smoke when burned. This prevents spoiling of the flavor. It requires an expert to cook the pill. When the mass is heated, it softens and is then shied. By this is meant the stringing or pulling of the mass. The shied mass is again rolled on the yen hok and heated. Next, the bowl of the pipe is heated and the warm mass quickly applied around a small opening of said bowl. The smoker quickly draws on the pipe. Only one or two pulls may be taken from a pill. The bowl must be kept warm. When all are smoking, the group resembles a wheel, with the pipes as the spokes.

After smoking, a cake is found in the pipe which is dark brown in color and brittle in consistency. This mass is known as yen shi or opium ashes. It is bitter in taste and has a peculiar sweetish, sickening odor. It is eaten by some addicts and is also used by the Chinese to flavor raw opium. Morphine is derived from opium and heroin is obtained from morphine. Addicts of opium and its derivatives use the drug only for its effect upon the nervous system.

Briefly the action is as follows: Opium stimulates the intellect, imagination, associations, all of pleasurable character. The reality of life in its sterner phases, is viewed and interpreted from an illusive standpoint, creating a subjective and objective reality where cares and sorrows are submerged, a self-contentment, a mental utopia—in other words, the euphoria of the poppy. This is followed by a dreamy state, due to suppression of external

stimuli, resulting in sleep. The subject has fantastic dreams, often of an impossible nature. The sleep is deep and the person is not easily aroused. The pupils are contracted and react very suggishly to light and accommodation. After a person has taken the drug for years, there may not be a contracted, pin-point pupil. The muscles seem to become inactive and do not react to the drug any longer. For this reason, the pupillary condition is not a reliable diagnostic sign in older cases. All other reflexes are first stimulated and then depressed. After the cessation of the action the individual is dull, restless, and unable to concentrate his thoughts. Such individuals lose all ambition. Perversion of the moral sense is a marked symptom. Delusions may occur and some prisoners show marked hallucinatory excitement. The reflexes are exaggerated, due to the removal of the depressant action of the drug upon the spinal cord. The action of morphine and heroin is similar to that of opium, but greater in degree. This is particularly true of heroin. This latter drug is several times as powerful as morphine. The chemical name of heroin is morphine diacetic ester.

Cocaine is a white crystalline powder, inodorous, which has a slight acid reaction and is bitter in taste. When placed on the tongue, it produces a tingling sensation, which is followed by numbness. Cocaine hydrochloride is derived from *Erythroxylon coca*. Its action on the nervous system differs from that of morphine. This drug stimulates all the mental faculties and produces a great increase of bodily power. As in the case of morphine, all external occurrences are ignored. All care and sorrow are forgotten and the person is supremely happy. Cocaine, however, does not stimulate the imagination as much as does morphine, nor is there any tendency to sleep. On the contrary, cocaine causes insomnia. One habitué told us that it was a common occurrence for him to go without sleep for seventy-two hours after taking cocaine. At the end of that time he was practically in a condition of collapse. The stimulating effect of cocaine is followed by physical and mental exhaustion, enfeeblement of the intellect, and headaches. Cocaine acts upon the sympathetic and causes a dilatation of the pupils. Habitués, when in need of the drug frequently complain of a feeling of foreign bodies crawling under the skin. As regards the reflexes, these are increased or exaggerated during the period of stimulation. When the action of the drug ceases, a decrease in reflex activity is noticeable. The pupils react to light.

The pathological changes resulting from these drugs are worthy of mention.

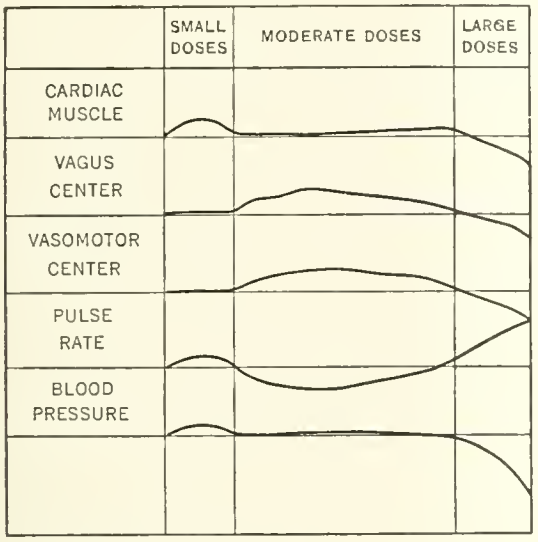
Gastrointestinal system.—As is well known, opium causes a decrease of all secretions excepting the sweat. It may readily be assumed that a continuation of such action for any prolonged period will result in atrophy of the gastrointestinal glands. Opium also decreases peristalsis, thereby causing constipation. Taking both the decrease in secretion and interference with peristalsis into consideration, it is obvious that absorption and assimilation are interfered with and that stagnation occurs. Consequently toxic substances are absorbed, giving rise to headaches, dizziness, and dulled mentality. People addicted to opium and its derivatives usually eat less than normal individuals. Opium appeases hunger. This, of course, is a factor to be remembered when we consider the great loss of weight that occurs in fiends. We have noticed that yen shi chewers lose weight more rapidly than opium smokers. This is also true of morphine and heroin fiends, particularly of individuals addicted to the latter, said drug being several times more powerful than morphine.

Respiratory system.—Narcotic addicts at the present period prefer to administer heroin and cocaine by sniffing. This method of administration leads to definite pathological changes in the nose, often resulting in perforation of the nasal septum at the union of the cartilaginous and bony portion. Upon beginning to sniff either cocaine or heroin, the nose feels clogged up when the effect of the drug wears off. The action of the drug when administerd by sniffing produces a sensation of numbness and coldness. This is due to the shrinking or temporary constriction of the blood-vessels of the nasal mucosa. Therefore, when the action of the drug wears off, there is a dilatation of the blood-vessels and swelling of the mucosa, resulting in clogging the nose. In order to feel relieved, the fiend takes another sniff. Later, there is no swelling after the action of the drug wears off. The mucosa becomes anemic and an ulceration forms at the union of the bony and cartilaginous septum. Continuation of sniffing eventually leads to perforation. We have seen several cases where complete destruction of the cartilaginous septum has occurred, with resultant caving in and deformation of the nose, somewhat resembling the saddle nose of syphilitics. Cocaine will produce a perforation in one year's time. A combination of cocaine and heroin will produce a perforation in less time. Heroin will produce a perforation when used for several years.

It is also noticed, as a rule, that drug fiends suffer from bronchitis. It is safe to say that at least three-quarters of all the drug fiends who have come under our observation and treatment have presented this condition. The explanation thereof is as follows: When morphine or heroin is taken, in physiological, or rather therapeutic, doses, the action is to depress the sensibility of the respiratory tract to reflex stimulation and to diminish the amount of bronchial secretion. The old law that over-stimulation results in depression is true in this instance. When a person takes these drugs continually for a long period, the above-mentioned action ceases. Consequently the drug acts as an irritant to the respiratory system, resulting in bronchitis with abundant expectoration. It is a well-known fact that fiends usually die of either tuberculosis or acute cardiac dilatation. We know that opium and its derivatives in large doses slow the respirations to four and six per minute. It is evident that a continuation of the administration of large doses of the drug can have only one effect, viz., weakening of the lung tissue. The amount of air taken in is diminished. The CO_2 of the blood therefore rises; CO_2 is a poison and results in diminishing the resistance. Taking into consideration the fact that fiends are usually neglectful of all else but the procuring of the drug, in consequence not eating regularly, etc., it is evident that they are more prone to tuberculosis than others.

Circulatory system.—The following diagram taken from Sollman's textbook of Pharmacology is illustrative of the action of the opium group on circulation. The late Prof. John H. Ripley used the official solution of morphine in attacks of diphtheritic paralysis of the heart. This restored the action of the heart to a great extent.

From the following diagram it is easy to see what large doses accomplish. A continuation of the administration of large doses can have only obvious results upon the circulatory system. Large doses result in paralysis of the heart muscle. When a fiend is deprived of the drug and suffers severe withdrawal symptoms (*vide infra*), he may die suddenly from an acute dilatation.



Genitourinary system.—Morphine is eliminated in the urine in the form of morphine-glycuronic acid. We have noted in several cases that there was a suppression of urine. Usually, however, no marked pathological symptoms referable to this tract occur.

Generative symptoms.—The action of the opium group on the system is marked. In males taking the drug the general rule is a loss of sexual desire. An erection may occur, but there is not much sexual inclination. If sexual intercourse is attempted, the act is usually futile, and where emission of semen does occur, it is usually accomplished after several hours' effort. When the drug is withdrawn, the sexual desire often becomes intense. People addicted to the drugs, upon withdrawal of same, have nocturnal emissions, and these are sometimes so frequent as greatly to weaken the individuals. Women are usually more strongly affected than are men. They also suffer from nocturnal emissions. One woman begged for bromides to quiet her, stating that she could not keep her hands from herself. Cocaine habitués are usually sexual perverts, and in them the sexual desire is extreme. In females when taking the drug (opium and its derivatives) habitually there usually occurs a cessation of menstruation. We have known women to give a history of cessation extending over years. The menses usually return when treatment is begun, and are sometimes very profuse and attended with severe abdominal and lumbar pains. What is the effect of addiction upon pregnancy? The following facts have been ascertained from the histories obtained of prisoners coming under our observation. Where both mother and father are addicts and under the influence of the drug, sexual intercourse is without result. Where both are temporarily off the drug and are sexually excited, impregnation may occur. If both return to the drug, one of two things may happen: (*a*) miscarriage; (*b*) birth of a child which may be dead or else if it lives, is of a weakened constitution. The addicted mother should not nurse the child. If she does the child will become addicted through the milk. We have the history of a case where a child, eight months of age gave all the symptoms of drug addiction. It seems that heroin does not decrease the secretion of milk as much as does morphine. So long as the mother took heroin the amount of milk secreted was plentiful, but as soon as morphine was taken the amount secreted diminished rapidly. We have failed to find reference to sexual changes in the literature treating with drug addiction. The effect upon the generative organs we believe to be of evident importance.

Mentality.—Drug fiends as a rule are neurotics. The psychoses noted in addicts are often similar to those seen in alcoholics. In the latter, the characteristic features are delusions of marital infidelity and of persecution. The following cases will illustrate this point:

People vs. C. H. C. H. was a woman and a confirmed addict. While under the influence of opium she killed her husband, whom she accused of marital infidelity. These delusions were also present while she was in the Tombs. She was sent to Matteawan, and is there at the present time. This woman showed marked sexual hyperesthesia and begged for bromides to quiet her passion. After killing her husband she attempted suicide while suffering from the above-mentioned delusions.

People vs. N. C. N. C. was also a confirmed addict. He also had delusions of marital infidelity. While in the Tombs these delusions were inhibited as far as could be ascertained, by talking with the man. However, our attention was called to these delusions by letters written to his wife by him, said letters being referred to us. These showed the trend of his delusions. In fact, all these accusations were written by the prisoner in red ink, whereas the other part of the letter was written in black ink.

Several of our cases showed marked delusions of persecution. One prisoner in particular became very violent and required several hypodermic injections of morphine to quiet him.

Are all drug addicts of lowered mentality? Absolutely not. It is true that opium and its derivatives dull the mentality. However, all addicts are not placed in the same position socially, nor are all addicts fiends (*vide supra*). The addict who has plenty of money and many friends, and in consequence better social surroundings, cannot be compared to the fiend who hangs out in the dens and just lives to smoke. The first mentioned are usually well nourished and take just enough of the drug to satisfy them. The latter are never satisfied. If any mental defectives are to be found they are found in the latter class. Obviously, immediately after awakening from sleep produced by opium, the mentality is clouded, but this soon wears off. Krafft-Ebing, in speaking of the action of poisons on the mentality, says: "Morphine never injures so profoundly the psychic organ as alcohol does, but I have never seen a morphine addict who was psychically intact. Intelligence it is true, is practically spared, character and ethical feeling, the highest mental functions, also mental energy and force always suffer. The fully developed morphinist is an individual weak in character and will, and without energy, who would receive under criminal prosecution, the benefit of the extenuating circumstances, and who in the care of his interests and duties should always be given help."

In a letter written to the Hon. John J. Freschi, then a magistrate (September 19, 1912) on the subject relating to a proposed amendment of the section in the Inebriate bill with reference to the disposition of drug addicts the above-mentioned state-

ment of Krafft-Ebing was included. We must, however, differ from the author when he states that he never has seen an addict that was psychically intact. Our experience teaches us differently. Mental energy and force may suffer in fiends, but to say that this is also true of addicts who smoke for pleasure is contrary to our experience.

In discussing the mentality of addicts we must not forget to mention that these individuals are unbelievable. Former Deputy Commissioner Wright describes a man who was brought to his notice by the warden. The prisoner was accused of trying to procure drugs from outside sources. When questioned he swore he never had used drugs and in fact did not know what heroin and morphine looked like. The man was searched, and in the seams of his trousers was found concealed a deck containing enough heroin to satisfy his craving for several days.

Drug addicts may be dulled mentally in some instances, but when the problem is one of obtaining the drug, these people are the cleverest and most cunning of all people. As is well known, it is almost impossible to smuggle opium or its derivatives into the Tombs. In spite of all precautions, some does get through. Some of the attempts made are as follows: On one occasion two books were sent to an addict; the keeper searching the packages examined the pages from cover to cover and could find no signs of drugs. Deputy Commissioner William J. Wright happened to be in the building and saw the books. He picked one up and noticed a white powder on the desk. He then searched the book but could find nothing. Taking out his pocket knife he ripped up the binding of the books and discovered a package of heroin concealed in each. On another occasion a woman came to visit a drug user. She was searched by the matron, all her clothes being stripped from her. Nothing could be found. And handing the woman her hat, the matron noticed the rubber end of a pen filler on the end of the hat pin, the same having been concealed beneath the plumes. This contrivance, when examined, proved to contain a large dose of morphine.

On still another occasion a woman was arrested, charged with having drugs in her possession. When searched, no drugs were found. She was then turned over to the doctor, who upon vaginal examination discovered a case containing an entire hypodermic outfit, including several tubes of morphine tablets. On many occasions drugs have been found concealed in the vagina. On others we have found condoms full of heroin or morphine concealed in the vagina, and on one occasion a finger cot with morphine in the rectum, with a string attached, protruding from the anus.

Another mode of smuggling the drug is in food. Oranges have been sent to users of the drug which upon examination proved to be loaded with a solution of morphine. The drug had been injected by means of a hypodermic. One addict attempted to send the drug into the prison in a can of condensed milk. We have in our possession two packages of cigarettes, which are loaded with morphine tablets.

Finally, in speaking of the effect upon the mentality, we must not forget to mention the yin yen. By this is meant the periodical craving for the drug. This, of course, is purely a psychic phenomenon, and is most often noticed in individuals when they are "getting off" the drug. At such times they will beg piteously for the drug.

Other changes produced by the opium group.—It has come to our notice and has been demonstrated to other physicians by us that many of the women habituées present a wonderful growth of hair. On one occasion a prominent physician visited the Tombs and while discussing this subject said physician seemed sceptical as to this fact. We took him to the female prison and had two addicts brought out, who let down their hair and dispelled all doubt as to our statements. It is no exaggeration to state that these women each had hair which extended to the calves of the legs. Not alone was their hair long, but thick and oily. We can think of only one explanation of this fact. As is well known, opium and its derivatives decrease all secretions excepting the sweat. The sweat glands are stimulated. Histology of the scalp teaches us that numerous sweat glands are distributed to the scalp and the roots of the hair. Opium and its derivatives by stimulating the glands increase the moisture of the scalp, thus causing a greater growth of hair. It is purely a nutritive process.

Hypodermic fiends at times present frightful skin lesions. The body appears to be covered with a rash, due to the use of the needle. At other times abscesses are noticed, filled with foul pus. Fiends do not sterilize the skin and needle before injection, and in most cases inject the liquid through the clothes. In the Tombs, the fiend manufactures his own hypodermic. The rubber portion of a fountain pen filler is attached to a hypodermic needle. This makes a very serviceable syringe. The fiend passes the syringe to the others on the tier. I have known syphilis to have been transmitted to four individuals by this means.

Drug addicts, when unable to obtain the drug, suffer severely, as in the withdrawal stage. We usually find them lying in bed and yawning very frequently. Lacrymation and running of the nose are invariable signs. Sometimes the individuals cannot stop sneezing. They seem to be itching all over, and are continually rubbing the arms and legs. In some of the severer cases the patients vomit and are affected with diarrhea, which is at times bloody. The body is covered with a clammy perspiration. The pupils are dilated and react sluggishly to accommodation and light. The patient may be unable to void urine. Women often have profuse menstrual discharges and severe abdominal pains. Abdominal pains are also present in the men. The pulse varies between 100 and 140, is of low tension, and sometimes irregular. Insomnia is present in all cases. In both males and females sexual excitement may be intense, and nocturnal emissions may occur. Some patients present delusions and hallucinations. The reflexes are all exaggerated excepting the pupillary.

Cocaine fiends show no withdrawal symptoms. Opium smokers seldom show any withdrawal symptoms excepting the yin yen. The withdrawal symptoms are usually noticed only in morphine and heroin addicts.

In cocaine fiends the following are usually noticed: loss of weight, mental fogging, exhaustion, insomnia, spasmodic contractures of muscles of the extremities and acceleration of pulse. These individuals are usually anemic, have a dry, sallow skin, and a peculiar glistening look in the eyes. The withdrawal symptoms in one who has used both cocaine and heroin are more severe than in one who has used heroin only. The combination of cocaine and heroin is very destructive as regards both the

physical and the mental condition of the individual.

How is the habit acquired? From the histories of the prisoners we have ascertained the following: Very few drug fiends traced their addiction to physicians' prescriptions. In fact it is a rare occurrence for us to obtain such a statement. Those who do give such a history are most often women who have suffered from tubal disease or severe burns and cancer. Among men giving such a history the majority are affected with locomotor-ataxia or cancer. The majority of prisoners, however blame their addiction to friends. Drug addiction has become so prevalent that there is scarcely a poolroom or saloon that may not be termed a drug fiend's "hang out." The profit reaped by dealers in narcotics is so enormous as to warrant certain conspiring individuals to chance arrest. Almost always, the addict is fooled. When he buys a deck "60-grain powder," he is sure to receive three-fourths sugar of milk. Janitors, cabdrivers, and bartenders have become agents, for certain individuals have found that drug selling is a very profitable business. These men are known as go-betweens.

Some people take the drug for insomnia. This is particularly true of nurses and physicians. Such cases have come under our observation and treatment. Others take the drug to ward off sorrow and care, while some are compelled to take the drug because of the severe pains caused by locomotor ataxia, cancer, etc.

It is a noticeable fact that most of the addicts coming under our treatment are young indivduals. It is not uncommon to find boys and girls sixteen and eighteen years of age who give a history of having taken the drug for two years. We have treated one child, who became a confirmed drug fiend through the mother's milk.

Concerning addiction among the different races, we have ascertained the following:

Yellow race: Compared to all other races arrested for various crimes, the Chinese are probably the fewest of criminals. However, those who are arrested are for the most part addicts. The particular drug used is always opium and its ashes, yen shi. We have never seen a Chinese hypodermic fiend or sniffer.

White race: Next to the yellow race in the proportion of prisoners is the white race. These are chiefly Hebrews and Italians. The former compose from 30 to 50 per cent. of the addicts, the latter from 20 to 30 per cent. The remainder are chiefly Irish. The drugs used by the white race are heroin, morphine, opium, and cocaine, in order of frequency. From 80 to 90 per cent. use heroin.

Black race: Prisoners of this race are mainly addicts of heroin, cocaine, and opium smoking, in order of frequency. It is rare to see a colored hypodermic fiend. Down south the negro is addicted mostly to cocaine.

As to the occupation of individuals addicted to drugs, we have ascertained that none of the habitués are engaged in what may be termed laborious work. The occupations given among them are actors, clerks, chauffeurs, artists, and song-writers. Among the females we find solicitors, actresses, nurses, and stenographers.

As regards nationalities, we must state that it is rare to see a foreigner, with the exception of the French, who takes the drug. By foreigners we refer to those individuals who have been in this country but a short while. We have, however, treated several Syrians and Greeks. Most of the addicts are American born, or have been in this country for years.

As regards social standing, it may be stated that addiction exists among all classes. Individuals from Fifth Avenue often mingle with those of the Bowery, and when under the influence of the drug are on the same moral and mental plane as are the fiends of the underworld.

In conclusion we wish to state that we do not desire to discuss any particular form of treatment. We wish to state most emphatically, however, that having taken the physiological action and pathological changes incurred by the drug into consideration, we are compelled to state that we do not sanction any treatment that employs depressant drugs, to gain what is commonly advertised as a cure. The individual may be taken off the drug by any of the advertised methods, but at what cost? The treatment sometimes acts like a torch applied to a barrel of gunpowder. If the patient before being treated, has a slight tuberculous focus, he is sure to have an extensive one following some of the widely advertised treatments. If he has a latent nephritis, this is certain to become a very active disease. If a cardiac condition with compensation exists before treatment, the individual may die during the treatment, and if not, is left with an incompetency following the "cure." Such individuals when dismissed and turned onto the street in their weakened condition, will follow the line of least resistance, *i.e.* they will go to the first place they can reach to get some "dope" to strengthen themselves with. The treatment we have employed consists in rapid reduction, accompanied by supportive treatment. In all our experience we have never had a single death and have never had a patient who did not gain some weight. In fact, we have had patients who gained from 40 to 50 pounds in two months' time, this period including the actual treatment and after-care. We wish to state most emphatically that one cannot cure a drug fiend in two weeks or in two months. All one can hope to accomplish is to take him off the drug. Following the treatment, the patient should be sent to a farm or some institution, outside of the city where he will be away from bad company and from sources where he may obtain the drug. He should stay away for a period of from six months to one year. This is the only method that can lead to permanent and good results.

We advocate that the following facts be ascertained before actual treatment is begun: (1) Physical condition of the individual. (2) Kind of drug used by the individual. (3) Daily amount taken. (4) Social condition.

No physician should be allowed to treat a patient outside of a sanatorium or hospital. The so-called reduction cures given by physicians, allowing the fiend to work and attend to all business, permitting contact with evil associates, are of no value and should be prohibited by law.

The reduction treatment is the oldest and in our opinion the best treatment. The Chinese have employed a reduction treatment for many years. This consists of two bottles containing red coated pills. One bottle contains opium pills and the other are plain pills. The Chinaman is told how many to begin with and gradually reduces the amount until "off the drug." This treatment is not carried out in a sanatorium, and therefore very good results have not resulted. Osler, in speaking of the treatment of drug addicts, states: "Isolation, systematic feeding,

and gradual withdrawal of the drug, are the essential elements. As a rule the patient must be under control in an institution, and should be in bed for the first ten days. It is best in a majority of cases to reduce the morphine gradually. Usually within a week or ten days the opium may be entirely withdrawn. In all cases the pulse should be carefully watched and if feeble, stimulants should be given. It is essential in the treatment of a case to be certain that the patient has no means of obtaining morphine."

In connection with the last statement we refer our readers to the early part of the article. When drug fiends enter the Tombs every bit of clothing is taken from them and thoroughly searched. All mail, clothing, and food are thoroughly searched. Female addicts are in addition given a vaginal examination by the physician.

Forchheimer (Prophylaxis and Treatment of Internal Diseases) states: "In order that the best results be obtained the patient must be confined to bed and have a trustworthy attendant. Where the conditions are proper, the patient may undergo the weaning from morphine at home. This is not a favorable way. For even in hospitals and institutions the patient frequently circumvents all precautions taken to prevent his obtaining morphine. A morphinomaniac has lost his moral sense; he can never be believed, and besides, on account of the suffering attending the withdrawal of the drug, he will try to get morphine at any cost, using all his ingenuity to this end in the most unscrupulous manner. Before he enters the room in which he is to be treated, he should be carefully examined. Closets, bed clothing, indeed every nook and corner; the patient himself must be stripped and all his belongings searched for morphine."

This author also advocates the reduction treatment, the patient being under constant observation.

Among others recommending the reduction treatment are Dieulafoy and Strümpel. Almost every textbook on medicine recommends this method.

Being in the city employ we have frequently been asked for recommendations as to methods advocated for curbing the drug habit. We cite the following and hope that our recommendations will receive the earnest attention of our readers.

It is an evident fact that a State law will never in any way curb the drug habit. The Boylan law is a failure in this respect. People who want the drug simply go to New Jersey or Connecticut and obtain as much of a supply as is desired. At present a State law is being recommended, and we venture to state that it will meet with just as much success as did the Boylan law. The Harrison law has also proved a failure. Unscrupulous physicians have added greatly to their material interests while strictly adhering to this law. The law is full of loopholes. The one dollar tax imposed on physicians practically places us on a level with saloonkeepers. The imposing of such a tax does not act as a deterrent upon drug addiction. If a proper Federal law be enacted we will be doing something to curb the drug evil. We believe the following would be such a law: 1. All narcotic drugs and their derivatives coming into the United States to be placed under the supervision of the United States Public Health Service. 2. The United States Public Health Service is to sell or dispense of these drugs to the State Health Service of each State, record to be kept of same. 3. The State Health Service is to sell or dispense of the drugs to the Board of Health of each city, record being kept of same. 4. The Board of Health to have stations in each district, open day and night, at which places physicians and druggists may obtain the drugs, a record being kept of same. 5. The establishment of dispensaries or receiving stations, where addicts may apply for treatment without fear of arrest and from which place they may be sent to certain designated hospitals to take the treatment. 6. The establishment of farms to which these addicts may be sent after being taken off the drug, and where they can remain for at least six months. 7. To make it a criminal offense for physicians to treat patients outside of a sanatorium or while at large, without constant watching.

The Hon. Katherine B. Davis, also the Hon. Burdette G. Lewis and the Hon. David Kelly have tried their utmost to establish farms for drug fiends, and have been successful in obtaining a farm at Warwick.

What is the percentage of addiction in the Tombs? Undoubtedly our statement will cause surprise in view of the fact that so many hysterical statements have recently been made and published. Those actually giving a history of addiction and requiring treatment comprise 5 per cent. of the inmates. This is a liberal percentage. We do not count those as addicts who are arrested for selling the drug or those who have taken the drug on one or two occasions, but have never made a habit of it. Two years ago our percentage was only approximately 3 per cent., showing that addiction is on the increase.

People have also entertained the belief that all homicides are drug users. We have found the following to be the crimes committed by addicts: In order of frequency these are petit larceny, grand larceny, attempted suicides, exposure of person, forgery.

Pleasure smokers rarely commit crimes which may be traced to drug influence. Fiends commit the crimes above mentioned, and usually the reason given is that the money stolen was to be used to obtain the drug. In regard to Krafft-Ebing's statement (*vide supra*) we wish to state that we partially agree with the statement which says, "The fully developed morphinist is an individual weak in character and will, and without energy, who would receive under criminal prosecution the benefit of the extentuating circumstances and who in the care of his interests and duties should always be given help."

We feel also in discussing its medicolegal relations that the line should be drawn sharply between those addicts who had borne a previous good character and who had become addicts from physical causes *i.e.* insomnia, locomotor ataxia, etc., to aid them at their work, as they say, and where some degree of relationship can be established between the act charged and the drug addiction, not legal insanity as we understand it, but a lesser degree of responsibility, as implied by the mental state induced by the drug. We differ from Krafft-Ebing in the general application of the above to all addicts who commit crime, but would confine it to the class as above described, who are essentially distinct from those who acquire the habit through criminal associations.

In conclusion, we wish to state that the present article is based entirely on our observations and treatment of cases, and we feel that we have demonstrated several facts hitherto unpublished. To recapitulate:

Opium and its derivatives and cocaine lead to the

following: (1) Perforation of the nasal septum. (2) Impairment of the sexual organs and of the power of generation. (3) Impairment of moral sense. (4) Impairment of the mentality. In hypodermic fiends we find multiple lesions of skin and formation of abscesses. Opium addiction is a causative factor of tuberculosis and bronchitis. It affects the cardiac muscle leading to cardiac dilatation. It influences the nutrition of the scalp, causing increased growth of hair.

We take this opportunity to thank Warden John J. Hanley and the keepers of the city prison for their courtesy and aid in obtaining the data above quoted.

THE PHYSICS OF PERCUSSION AND AUSCULTATION OF THE CHEST.

By FRED H. HEISE, M.D.,
TRUDEAU, N. Y.
RESIDENT PHYSICIAN, TRUDEAU SANATORIUM.

Percussion and auscultation are based primarily on the production and interpretation of changes in sound; consequently these two methods of diagnosis are intimately connected with, or governed by, the physical laws applying to sound. And it will not be amiss to define sound briefly and to state some of the simpler laws governing its character, production, conduction, etc.

Sound is the sensation produced through the ear by vibrations, either of a vibrating body itself or the surrounding medium. Sounds may therefore be said to be wave vibrations interpreted by the ear, just as light is wave vibration interpreted by the eye. Sound waves may differ in three ways: (1) the rate of propagation or number of waves per second; (2) the amplitude of each wave; (3) the form, that is whether simple or compound. In other words, sound waves as heard by the ear may differ in pitch, intensity, and quality.

The number of waves per second determines pitch. If the waves are long and few in number the pitch is low, and as the number increases per second the pitch becomes higher and higher, until the sound is very shrill and piercing and finally becomes inaudible. It has been found that to be perceptible as sound the vibrations must be no fewer than 16 to 24 per second, nor more numerous than 30,000 to 40,000 per second.

Intensity or loudness is dependent upon wave magnitude or amplitude, and diminishes with the square of the distance of the sounding body and also as the density of the medium through which it passes decreases.

Quality depends upon wave form, that is whether simple or compound, and distinguishes between the same tone when sounded upon two different musical instruments, such as a piano and a violin. It depends upon the number and intensity of the overtones or harmonics which blend with the fundamental note. These overtones are higher notes of small intensity as compared with the fundamental.

Sound waves are conducted, and may be reflected, refracted, diffracted, and interfered with or broken, giving rise to beats.

Sound waves are not conducted in a vacuum. A medium for conduction must be present. In this medium the waves travel in all directions, with a velocity or facility depending upon its physical nature and temperature. In air the velocity is about 1090 feet per second at 32° F., and increases as the temperature increases. In other cases the velocity varies inversely as the square root of the density. In liquids the velocity is greater than in air (in water 4 times greater). In solids the velocity varies greatly, being small in inelastic substances such as lead and wax, and quite great in substances like wood and steel (2 or 3 miles per second, or about 10 to 15 times as rapid as in air and 3 to 4 times as rapid as in water.)

The laws governing reflection and refraction of sound are the same as those governing light. The echo is a sample of reflection. Owing to the rapidity with which sound travels in air, 1090 to 1125 feet per second, and to the fact that approximately 1 9 to 1 16 of a second must elapse between sounds for them to be appreciated as distinct and separate sounds, the hearer must be at a distance of approximately 60 feet from a reflecting body to appreciate an echo. For this reason echo plays no prominent part in auscultation and percussion.

When a sound wave meets the surface of another medium of greater density it is in part reflected, travelling back from that surface into the first medium with the same velocity with which it approached. When a sound wave travelling through one medium meets a second medium of a different kind the sound waves are communicated to the second medium with a velocity and direction depending upon the density and elasticity of this medium.

Sound may be amplified or increased in intensity by resonance. By this is meant the prolongation of sound by reflection, or the prolongation and increase of sound by sympathetic vibration or other bodies. This sympathetic vibration is in unison with the fundamental tone or one of its harmonics. The pitch and quality of the resulting sound are largely dependent upon the shape and size of the resonant chamber.

Having considered in a general way a few of the laws governing sound, let us now consider the anatomical construction of the chest and see what bearing this has on sound as produced by percussion and as heard upon auscultation.

The chest is a bony and cartilaginous framework covered by muscle tissue, fat, and skin, and enclosing the lungs, heart, and mediastinal tissues and structures. Separating the chest from the abdomen is the movable diaphragm. Between the ribs are interlacing muscles, allowing considerable movement. Covering the ribs according to physical development and nourishment there is a varying amount of muscle tissue and fat. Lining the ribs on the inside is a smooth reflecting surface, the pleura, and enclosing the lungs is another such surface.

The lungs are made up of spongy, elastic tissue, the air cells and bronchial tubes of various calibre and size, the more minute ones not having any cartilage in their walls and the larger, from the fourth division upward, having cartilage (Leaming) and being more rigid. These tubes are set at all angles to one another, and are therefore not arranged according to acoustic principles. Accompanying the bronchi and around the air cells are also many blood-vessels of varying sizes. Connecting the lungs with the mediastinum are the larger bronchi and blood vessels. And the larger bronchi terminate in the trachea, which leaves the mediastinum and ends in the voice-producing larynx. At the base of the chest is the diaphragm, which permits considerable variation in chest or lung volume. Owing to the conical shape of the chest and the presence of only a

little cartilage in the apex, this part is much less movable than the base.

Percussion.—The chest in health is a very good resonator. It is said that the violin was fashioned after it. Certainly the air contents when set in vibration amplify the sound and give it a quality dependent upon the physical state of the lung at the time being. What is the percussion note? It is the resulting sound we hear when striking the outer covering of the chest or the walls of the resonator. This sound is produced by vibrations originating in the chest wall, travelling through it to the resonating chest, reflected backward through the wall and into the surrounding air. It is true that a part of the sound travels only through the air to our ear, but this part necessarily lacks chest resonance. Originating in and travelling through the chest wall, the sound upon percussion must be modified by the physical state of the various tissues comprising the wall. Considering the resonating chest as a constant, that is having a constant volume of air, what external causes affect the note heard on percussion? The thickness of the chest wall, the quantity of fatty tissues and the state of contraction of the muscle tissue and skin. If the chest wall is very thick a hard blow is necessary to cause vibrations to reach the lung with sufficient intensity to be reflected again. So that with ordinary percussion no resonance results. Fatty tissue is a poor conductor of sound because the rate of propagation is slow. Therefore a large proportion of fat will successfully block vibrations unless the force originating them is great. When the muscles and skin are much relaxed, density diminishes and conduction is diminished. The vibrations may not reach the lung. Also, as in the case of a violin string too loosely strung, the vibrations may be too slow to be appreciated. On the other hand, when the muscles and skin are contracted and tight the resulting vibrations are rapid and the note is high pitched, just as the violin note is higher pitched when the string is tight than when it is loose. Some of the percussion note variations caused by the physical state of the muscles covering the chest are used by some men as an aid in diagnosis (Pottenger, etc.).

With the wall of the chest constant, how may internal chest conditions alter the percussion note? By alteration of the volume of air in the lung, by replacing a portion of the air set in vibration by a more solid substance and by interposing non-air-containing substances between the source of vibration and the lung. In other words, by destroying a part of the resonating chambers or by making them inaccessible to vibrations. These conditions may be brought about by ordinary inspiration and expiration, emphysema, atelectasis, infiltration, consolidation, new growth, thickened pleura, effusion, etc. In addition to these, air may be interposed between chest wall and lung. In each condition, according to the amount of air accessible to the vibrations, the resulting note will be low and resonant or high and less resonant, or not resonant at all, since the larger the resonating chamber the lower its fundamental, and it is the fundamental note with its overtones which is consonated.

Cornet states that on the surface of the lung tuberculosis areas cause an impairment of note only after reaching a size of 4 to 6 cm. and a depth of 2 cm.; dullness is produced only when the depth reaches 5 cm.; and that areas lying deeper than 5 cm., in other words having more than 5 cm. of normal lung between them and the chest wall, may easily escape detection by percussion. With this in mind and also the various causes influencing the pitch and resonance of the percussion note, it is difficult to see how minor changes can be of as great significance as some would lead us to believe.

Auscultation.—During auscultation we listen for what we term the breath sounds. These come to us from the lung through the walls of the chest. As we inspire, air is taken through the larynx and trachea into the larger bronchi and then through the smaller bronchi to the alveoli or air cells of the lungs. Coming through the larger tubes and those of smaller calibre which have rigid walls the friction of the air against the sides of the tubes causes vibrations and these are carried with the current of air into the lung. The air, in passing an open tube and by being impinged on angles of bifurcation, likewise give rise to sound and this is carried and conducted. It is said that after the air reaches the fourth division of bronchi no friction is caused, since the tubes of smaller calibre possess no cartilage, nor have rigid walls, and that the interchange of air further in the lung is by diffusion. During its course to the alveoli the air is warmed, causing an increased power of wave propagation. The alveoli or air cells are elastic. Each is in itself a small resonator. As it dilates it gives rise to sound, and within certain limits as it dilates the sound is proportionately amplified. It is the combination of sounds caused by friction, conducted along the tubes and the dilating air sacs, which makes up the inspiratory sound. When the air sacs collapse sound is again produced and friction sounds are caused in its outward passage, but here the current of air is in the opposite direction from inspiration.

According to Baas the breath sounds are modifications of the laryngeal and tracheal sounds only. According to Laennec they are caused only by the friction in the bronchioles and infundibula. According to Bueri they result from the friction of central and peripheral air volumes.

It is said that conduction within the lung takes place only in the direction of the tubes. The air in the lung not in the tube current is a poor conductor. The chest is a resonator. Helmholtz, Müller, and others have determined its fundamental note as a low one. Air conducts the lower sounds more readily than the high ones. The spongy lung dampens high tones more than the air alone. The tracheal and bronchial pitch is high, so that a layer of normal lung deadens these sounds almost completely. On the other hand, solids conduct the higher tones better than air tubes of the same length, consequently when the lung approaches solidification better conduction of tracheal and bronchial sounds takes place. Vesicular breath sounds are of low pitch only. Heart sounds are dampened by normal lung tissue in all areas except where the heart lies in close proximity with the chest wall. However, there the sounds are conducted by the mediastinum.

The shape of the chest partly determines the quality of sound. But inasmuch as respiration is largely a voluntary act intensity, and to a less degree pitch, must be relatively dependent upon the character of the respiration. However, other things being equal, intensity is dependent upon force or respiratory rate, and pitch upon the physical state of the lung (Quimby).

What are the modifications in breath sounds that may be experienced when alteration in the function and physical state of the lungs and adjoining structures takes place? These may be briefly summarized in the following:

Alterations in the intensity of inspiration and

expiration, alterations in the relative duration of inspiration and expiration, alterations in pitch and quality of both sounds.

Alterations in intensity may be brought about voluntarily or involuntarily. When the change is involuntary it is due to a change in the function of breathing or to a change in sound conduction. In the first instance there may be a partial atelectasis which does not permit the lung to take in as much air as is otherwise possible, or on account of partial obstruction in one of the larger tubes respiration is more labored. This last occurs also when the air sacs are dilated and kept so through spasm of their muscles and degeneration of their elastic tissue. In the second instance, that is when due to change in sound conduction, intensities belonging to the larger tubes may be transmitted more readily than normal and add to the intensity normally heard at the periphery. Or conduction of the sounds may be impeded by interposing media between the ear and the source of sound, as in pleurisy with effusion.

Normally inspiration is longer than expiration. The ratio has been variously estimated as low as 2 to 1 or as high as 4 or 5 to 1. The air in entering the lung travels toward the ear of the auscultator, and impinges itself on the angles of bifurcation. Inspiration is consequently more intense and of longer duration than expiration, during which latter act the column of air travels *from* the ear and impinges itself only with another column of air on the sides of the tubes. Anything which delays the normal collapse of the air cells or obstructs the outward passage of air will prolong expiration. This may occur in emphysema, or in partial paralyses of the air cell walls as in tuberculosis, or by foreign bodies having a valve-like action.

I have said that the normal vesicular breathing was low in pitch and the tracheal and larger bronchial pitches were high. Theoretically this should not be so. The trachea is large in lumen and longer than any of the tubes further along the respiratory course. Its note should be low. And as we proceed further into the lung the note should become higher and higher, reaching its highest pitch in the terminal bronchioles. The sound heard at the periphery of the lung should therefore be high in pitch. However, most observers state that the vesicular murmur is low and bronchial respiration high in pitch. Why this should be so I am unable to state positively. However, it may depend upon the fact that air conducts lower tones better than high ones and that the spongy lung dampens higher tones more than low ones. In this way possibly the higher tones are lost except when by increased direct conduction through solids which transmit high notes readily we hear them as happens when we listen directly over the trachea or bronchi, making the latter respiration relatively higher than the vesicular. Certainly we know that intensity diminishes as we proceed from the trachea to the bronchioles, in part because the force is divided and in part because conduction becomes poorer. Solids conduct higher notes better than air, so that when air has been replaced by congestions, new growth, etc., higher pitch should predominate in respiration.

As a general working basis we may say that intensity and pitch as heard at the lung margins are largely dependent upon sound conduction. Intensity diminishes as density diminishes and high notes are proportionately dampened and low notes relatively increased. Anything which increases the density along the respiratory channel will increase intensity and relatively increase the dominance of high notes in the lung margins.

However, intensity may be increased when cavitation is present. Here air is the conducting medium and amplification takes place in the cavity. The resulting pitch depends on the greatness of the resonating space, being low in large and high in small cavities.

Vocal Resonance.—Increase or diminution of vocal resonance depends largely upon sound conduction. Here the sounds formed in the larynx travel along the tubes to the periphery of the chest. Anything along the course of the bronchi affording increased conduction will give increased vocal resonance at the periphery of the lung. This condition is best brought about by an increase in density, as in infiltration, consolidation, new growth, etc. Or it may be caused by amplification within a cavity. On the other hand, conduction from the periphery of the lung to the chest wall must also be borne in mind since the interposition of certain media may interfere with or increase sound conduction. The first may be due to pleurisy with effusion, thickened pleura, air, etc., and an increased conduction to adhesions, new growth, etc.

In considering auscultation, that portion of the chest above the plane of bifurcation of the trachea must be considered in a different light from the portion beneath this plane, for in this upper portion lies the large trachea. And the anatomical position of the trachea, the acuteness and point of origin of the angles of bifurcation, and the length of each first bronchus—right and left—must be considered. These factors have a bearing on the sounds heard at the apices of the lungs. The trachea lies closer to the right apex. The angle of the (first) bronchus to the trachea is more acute and rises higher on the right than on the left. And the right first bronchus is shorter than the left. All of these factors would give to the respiratory sounds on the right more of the tracheal character, hence they are slightly broncho-vesicular. Also, vocal resonance therefore should be and is more intense.

Pleurisy with effusion reaching to this plane may give rise to increased vocal resonance throughout the area of dullness. And when the fluid falls below this level the increased vocal resonance disappears (Sewall). In a case of pneumothorax of the right side, with the lung entirely collapsed and with a small amount of effusion, breath sounds and increased whispered voice were heard by me when the patient was so inclined posturally as to bring the fluid into the apex.

Above the plane of bifurcation of the trachea, breath sounds from the trachea are well conducted by the bony structure of the chest. In two instances breath sounds could be heard above the second rib, and in one of these also above the third vertebral spine, after complete pneumothorax, as shown by *x*-ray, had been attained.

Bronchial breath sounds can normally be heard over the sternum to just below Louis angle, over the acromion processes (Barrach) and along the cervical and upper three dorsal spines. Increased whispered voice is also heard here, as well as far up on the cranium. This is in part due to bone conduction.

Rales and Adventitious Sounds.—These are produced upon and within the chest wall, upon the pleural surfaces and within the lung. We will speak only of those which are produced within the bronchi and air cells.

Within the lung these sounds are vibrations caused by a current of air passing along the respiratory passages to the air cells and meeting a partial resistance. The resistance may be due to partial or complete obliteration of the air cell or bronchus by means of collapse, mucus or fluid. Thus, for instance, the walls of the air cells or bronchioles may through atelectasis be in apposition, or they may be the seat of exudates, serum, etc. A forced inspiration will separate the walls of the air cells or bronchioles or set in vibration the serum or exudate; a sound is the result.

The resulting sound will vary in pitch according to the diameter and length of the air space in which the sound occurs. Vibrations within the smallest bronchioles will be high in pitch, and as the larger bronchioles and bronchi become the seat of origin the pitch will become lower.

The intensity of the sounds will vary with the force causing the vibrations and also with the quantity of the medium set in vibration.

The quality of the sound depends upon the physical state of the medium set in vibration and the resonance of the chamber in which the vibration takes place. Dilatation of the bronchi, or cavities, may give added resonance by reason of their increased air content. And by reason of the variable fluid level, increasing or decreasing the air space, pitch may be also changed.

Bubbling sounds are produced by the passage of air through a liquid medium, as happens in the case of cavities where the entrance of air is below the level of secretion.

Vibration within air spaces may also be produced by sudden changes in the position of the vibrating medium, caused by gravity or by pressure from without. Whatever may be the cause, intensity, pitch, or quality of the sound originally produced, it must before it reaches the ear be modified by the rules governing sound conduction which have already been referred to.

The definition of sound was given as "vibrations interpreted by the ear." The ear is a part of the individual, and by reason of anatomical or pathological variations the same sound may not be conducted alike to the brains of two individuals, or the two brains may vary in experience or education in their interpretation of sound, and consequently, although physics governs sound production and conduction, the personal equation governs sound interpretation—the one an exact science, the other a variable quantity. For this reason, percussion and auscultation are exact methods only within the limits of the human personal equation.

A NOTE ON POLIOMYELITIS, WITH ITS PREPARALYTIC SYMPTOM.

By LOUIS FISCHER, M.D.,
NEW YORK.

In the early stages of poliomyelitis we frequently have a sudden onset with a high temperature lasting several hours or days. There are headaches, pains in the back and limbs, and sometimes rigidity of the trunk and neck. The patellar reflex and plantar reflex may be exaggerated, diminished, or even absent.

As the pathological lesions are confined to the anterior horns, the pia mater, and the spinal cord, drainage of the spinal fluid is indicated as a means of diagnosis. The fluid of poliomyelitis so obtained is colorless. To differentiate the symptoms of poliomyelitis from those of an acute cerebrospinal meningitis, simple meningitis, or tuberculous meningitis, we should resort to a lumbar puncture. The spinal fluid should be carefully examined as to its color, its transparency, or turbidity. The presence or absence of pathogenic bacteria will aid in excluding poliomyelitis. Thus the tubercle bacillus will be found in tuberculous meningitis, and a staphylococcus, diplococcus, or influenza bacillus, in acute meningitis, or in cerebrospinal meningitis.

There is an increase of the leucocytic element, especially the polynuclear percentage, in the earlier stages of the disease, later a mononuclear increase. Still later we find 100 per cent of leucocytes. The globulin reaction in the beginning is negative, later it is positive.

A symptom of great importance, described by Dr. Draper of the Rockefeller Institute, is that flexion of the spine anteriorly produces pain and stiffness of the neck. The lymph glands of the body are enlarged.

An important symptom has been described by Culliver as a peculiar twitching, tremulous, or convulsive movement. It usually affects a part or whole of one or more limbs, the face or jaw. It may also affect the whole body. In the beginning, the symptoms may last less than one second, and do not recur oftener than every hour or so. Later, the spells lengthen to a few seconds, and recur at shorter intervals. The condition is sometimes accompanied by a peculiar cry, similar to the hydrocephalic. During the convulsive movement the child is apparently unconscious, with eyes set for a few seconds. A similar symptom has been described by Prof. Arnold Netter,[1] of Paris. This preparalytic symptom, if noted, will serve as a warning of the approaching paralysis, and, when observed, the limb should be strengthened by support to remove the weight.

The following case,

Jerome H., five years old, was seen in consultation with Dr. D. Paul Waldman on July 12, 1916. He was a fairly well nourished boy with a history of congenital syphilis. He was in apparent good health until six days ago when he was frightened by a dog. The dog did not bite him but licked his hand. The following day the child became languid and complained of headache. There was slight constipation. The appetite was fair. A slight papular and erythematous eruption was noted over the thorax, back, and upper and lower extremities, very little on the face. The temperature ranged between 103° and 104°. There was marked hyperesthesia of the skin with nervous quivering and twitching (preparalytic symptoms).

At midnight on July 12 the right arm became paralyzed, showing involvement of the brachial plexus. No other etiological factor could be made out. The sani-

[1]British Jour. of Children's Diseases, Dec., 1913.

tary surroundings are perfect. Hygienic supervision of the child's body and food could not be better. There had been no exposure to poliomyelitis as far as the family know. Nor could the family physician, Dr. Waldman, shed any more light on the etiology. Whether or no the susceptibility of the patient was increased because of its congenital syphilis is worth considering.

Examination showed the generalized eruption confined to the body—very little on the face. On stroking the skin with the fingernail a marked hyperemic flush remained visible for over ten minutes (the so-called tache cérébrale). The pupils responded to light and accommodation. There was an exaggerated plantar reflex, also exaggeration of the patellar reflex, and marked hyperesthesia of the skin at the slightest stroking of various parts of the body. There was an absence of rigidity of the sternocleidomastoid muscle. The right arm and forearm were limp, the surface temperature normal. A lumbar puncture made between the 4th and 5th lumbar vertebræ showed increased pressure of the spinal fluid and yielded a perfectly transparent fluid; 40 c.c. was obtained without difficulty. This fluid was examined by Dr. Abrahams at the Research Laboratory of the Health Department who reported as follows: mononuclears 80 per cent; albumin, 1 +; Fehling's 3 +.

The child rested comfortably after the puncture and the temperature came down to normal. Five grains of urotropin were given every four hours. Very light gentle massage was given once daily. A light soft nutritious diet consisting of milk, vegetables, fruits, cereals, and eggs was given.

Flexner has suggested the use of hexamethylenamine (urotropin), 3 to 5-grain doses every four hours, as a prophylactic to children in congested or infected districts. In all cases seen by me I have advised 3 grains, given morning and evening for several weeks, as it liberates formalin in the tissues.

There are three types most commonly met with: the catarrhal, the gastrointestinal, and the cerebral.

In the catarrhal type there is nasopharyngeal involvement, or bronchial catarrh, or symptoms resembling the onset of a pneumonia.

In the gastrointestinal type we have symptoms of overfeeding, or disordered nutrition, vomiting, constipation or diarrhea, and always fever. We should always suspect an abortive form of the gastroenteric type if a child, in spite of having its diet carefully supervised, suddenly shows gastroenteric derangement, with anorexia and a general apathetic condition.

The cerebral type is seldom met with in the abortive forms. I have never seen a case with convulsions and rigidity of the neck muscles that was not followed by paralysis.

The reflexes will be found slightly exaggerated, especially the patellar, plantar, and ulnar. In some cases seen by me the reflexes were greatly diminished for one day and found normal the following day.

The abortive type is the most common form, and, unfortunately, the one overlooked by the laity, because of the mildness of its symptoms. In many instances, the onset of slight sneezing, nasal discharge, and a temperature of 100° may be all the evidence of the poliomyelitis. Children convalescing from the abortive type are responsible for the spread of this disease. The symptoms being mild, the disease is overlooked.

Constitutional Effects of Deep Roentgen Therapy.—According to G. E. Pfahler in a small proportion of patients who receive large doses of rays, there develop constitutional symptoms consisting of nausea, occasional vomiting and a certain amount of prostration.

HYPOCHONDRIA.

By CLARENCE KING, M.D.,

FRANKLINVILLE, N. Y.

EX-PRESIDENT CATTASAUQUA COUNTY MEDICAL SOCIETY; LATER ATTENDING PHYSICIAN, CATTASAUQUA COUNTY HOSPITAL AND LOCAL SURGEON B. R. & P. RAILROAD.

TWENTY-FIVE or thirty years ago the word hypochondria was very much in evidence in medical nomenclature, but more recently it has had to give way to the trend of modern terminology. Beard's epoch-making neurasthenia has absorbed some of the symptoms formerly attributed to hypochondria, while melancholia includes some, and hysteria still others. In this paper I shall retain the nearly obsolete term as being old-fashioned enough for me and expressing just the condition I wish to describe.

No one who has been long in general practice has failed to meet with cases of nervous people whose minds were wholly taken up with magnifying their own ailments, either trivial or imaginary. These people are the terror of the doctor. It makes but little difference what is said or done for them, they are still ailing and are always in a deplorable condition, despite the failure to find anything of a tangible nature to account for their bad feelings. The main characteristic with them is the firm grasp which their ailments have upon the mental equilibrium, amounting almost to a self-centered insanity of the melancholic type. And indeed it has usually been considered that hypochondria should be classed with the mental disorders, rather than with the purely nervous or physical diseases.

Hypochondria is a disease of either sex, occurring in my experience with nearly equal frequency among men and women, the preponderance, if any, probably being in favor of the latter. It is a disease of adult life and occurs most often about the time of the climacteric in either sex. Mental worry with a natural pessimistic disposition, combined perhaps with overwork and some slight physical indisposition, are the usual precursors. A lowered state of health from any cause may undoubtedly predispose to it which only needs some strong mental influence to apply the finishing touches. Once developed it may continue a few weeks or it may pass over into a true melancholia and persist as long as life lasts.

Dubois, in his Psychic Treatment, states that "there is no longer any malady called hypochondria," and then immediately proceeds to devote more than two pages to its description. He gives as his definition of it "that condition of the patient in whom his naturally melancholic preoccupations are centered chiefly upon his health, and upon the workings of his organs." Thus it will be seen he classes it as a special form of melancholia, but it appears to me much may be said in favor of its being a distinct entity.

Hypochondria, as I see it, is a hybrid, a cross between melancholia and neurasthenia, but differing decidedly from either. Thus, with hypochondria it is often possible to get the patient to talk rationally and with a certain amount of cheerfulness on some subjects, or even to smile, but if left to his own inclinations his mind soon reverts to the melancholy aspect of his health; and in neurasthenia the condition is much the same. But in true melancholia the poor unfortunate cannot show much interest or any enjoyment in any subject even for a brief period. The gloomy forebodings as to business, social, or religious matters present with each

disease are much more decided in melancholia and predispose to suicide; but this danger is also present to some slight degree in hypochondria. On the other hand, in neurasthenia the patient seems to experience a certain amount of actual pleasure in dwelling upon and "doctoring" his imaginary ills, and self-destruction is therefore an almost unknown termination in uncomplicated cases. These, in my opinion, constitute the principal mental characteristics of the three diseases, although it must be conceded the line of demarcation is on all sides vague and indefinite and the discrimination between them in a given case is a matter of terms almost as much as of judgment.

Hypochondria, when it comes to the physician, is generally a chronic disease and has already run the gamut of home treatment, patent medicines, sympathetic neighbors, and often other doctors. But this may also be said of the other diseases, especially neurasthenia. On account of this there may be some anemia and general deterioration of the health, but a careful examination of the various organs and their functions will show little if anything out of normal. But the neurasthenic is sick physically as well as mentally, although the physical ailments are secondary to and dependent upon the mental weakness. The neurasthenic suffers much from nervousness, probably has disturbed sleep or insomnia, a poor appetite, functional inactivity of the abdominal and pelvic organs, especially of digestion, and a general loss of strength and weight. There is also apt to be dysmenorrhea or amenorrhea, a furred tongue, constipation, hemorrhoids, vertigo, exaggerated reflexes, various paresthesias, and often neuralgia of different nerve trunks, generally the sciatic, the vagus, or the intercostals. Melancholia, if it has lasted for any length of time, is marked by a peculiar facies of a dull and more or less idiotic type which we do not get with the other diseases. These, then, are the earmarks by which we must make our discrimination and which must guide us in our management of the case and our prognosis.

At this point I would like to bring this paper to a close but I know something should be said of treatment. This is difficult and usually unsatisfactory. Very often the patient drifts along as a chronic drug taker, unable to do any work or perhaps leave his bed, and finally develops some organic disease which closes the scene or makes a true physical invalid. I know of nothing better for these cases than change of environment; and travel with a cheerful and intelligent companion as chaperon or attendant will sometimes work wonders for them. This is for the purpose of occupying their minds and giving them something to think about outside of their own feelings. Suggestion holds a valuable place in treatment and the doctrine of good health or early improvement should be constantly preached to them by doctor and attendants. They should not be allowed to talk of themselves or refer to their ill health, but to circumvent this will require much tact and good sense. The late Dr. Gray of New York advised hypnotism as a valuable measure but of this I have no knowledge. If there was any way of instilling Christian Science belief by serums or other means it would be the ideal treatment, but as yet we have not quite reached that desideratum. Hydrotherapy in the form of colon flushings in the knee-chest position for the purpose of freeing the large intestine of putrefactive material or the cold spinal douche preceded by hot water fomentations, as advised by Baruch, may be of some benefit when it can be employed. These measures, together with high-frequency currents, general tonics, nerve sedatives, and placebos (and most drugs are placebos in this disease) constitute our only means of treatment.

One point of practical importance which I would mention in closing is this: Hypochondriacs are very apt to think that this and that article of diet "hurts them" and they keep cutting out the really valuable foods, one by one, until they have little left to subsist upon. When possible it is best to humor their whims to a certain extent, but they should not be allowed to half-starve themselves under any false notions about diet. Ordinarily, some simple stomach remedy or digestive, if prescribed with explicit directions as to its use and results expected, will make them more tolerant of food and do much to aid nutrition.

A CONSIDERATION OF THE OPSONIC TECHNIQUE AS A POSSIBILITY OF EVIDENCE OF LEUCOCYTIC INHIBITION.

By ARNOLD H. MAY, M.D.,

BUFFALO, N. Y.

THE work of Sir A. E. Wright has been instrumental in the practical application of ideas of the greatest value to humanity. It is, however, of scientific interest to review the opsonic technique with a consideration of another possibility being responsible for the phenomenon, which may be as potent in the production of it as is the presence of opsonius, and which may lead to the question of its infallibility as regards the proof of opsonius. The writer is not a laboratory man, and presents this merely because of the scientific interest it may hold.

The opsonic technique is performed in the following manner: (1) Serum of the patient + washed leucocytes + suspension of microorganisms.

Serum of normal individual(s) + washed leucocytes + suspension of microorganisms.

Mixtures of each of the above are made in specially provided tubes, and are incubated at 35° C. for about 15 minutes. Microscopic examination of stained slides of each of the above preparations is made to ascertain the phagocytic function of the leucocyte. The difference manifested in the phagocytic activity of the leucocytes Wright ascribes to the presence or diminution of bodies termed opsonius, which by their action upon bacteria facilitate phagocytosis. In the technique the effect of an immune serum upon a bacterial leucocytic combination not being included, it is not necessary to consider this phenomenon here.

In a consideration of this problem the fundamental nature of the leucocyte must be considered. The leucocyte primarily is a protoplasmic body, whose evident function is phagocytosis. Being a protoplasmic body it necessarily possesses the protoplasmic properties of irritability, metabolism (ingestion, digestion, and excretion) motility, reproduction, etc. It is not in appearance unlike the ameba, and many of its peculiarities lead to the name of amebocyte being early ascribed to it. Thus there is a marked resemblance between the two in the manner of locomotion, and the ingestion of particles, and it may be assumed that they likewise resemble each other in the matter of irritability. The protoplasm of the leucocyte is highly specialized, and it possesses an innate, very likely an evolutionary, predilection for these cells (bacteria),

whose existence in the body is inimical to the host. This faculty, which implies function, illustrates a higher degree of protoplasmic resistance to bacterial toxins than visceral cells functionating differently. However, not to transgress the object of this paper, and to bring in interesting but irrelevant facts, it may be said that the leucocyte is an irritable body, and is not always successful in its combat with bacteria, oftentimes succumbing or being devitalized by the bacteria. This could be anticipated from the fact that it is a protoplasmic body. Evidence of the fact that it is an irritable body, and that its function may be determined by its environment are easily obtainable. Thus non-virulent pneumococci are susceptible to phagocytosis, whereas virulent ones are not. The leucocytes not only succumb to but may be devitalized by toxins. This fact is illustrated by the work of Neisser and Weichsberg, who were able to prove by the reducing power of methylene blue by live leucocytes the injury wrought the leucocytes by a toxin called leucocidin, obtained from staphylococci filtrates. Various degrees of injury are wrought the leucocytes by this toxin. In short, then, the leucocyte is an irritable body, and may be adversely effected by environmental conditions in the same manner as any other cell, or as any combination of cells, which comprise the various manifestations of life.

Now, then, there remains to be examined the blood serum, which is the remaining factor in the technique. In disease there occurs a contamination of serum which is a factor proportional to the character (virulency, diffusibility) of the infection. The serum then obtained from the patient represents a contaminated serum, and proportionally as is the diffusibility and virulency of the disease process. The serum obtained from the healthful individual is normal noncontaminated serum. There are here, then, two essentially different sera, and into these are placed irritable, protoplasmic bodies, whose life and function, as has been shown, is directly dependent upon environmental conditions. Exclusive of any other factor, may not the inhibitory effect of a contaminated serum upon a body which is as sensitive as any other protoplasmic element be the determining factor in the slight deviation manifested in phagocytic capacity of these sets of leucocytes? To maintain that it may not be so effected is to deprive it of its property of irritability, which is amply attested to. Therefore may not another factor, exclusive of opsonius, the factor of a protoplasmic body reacting to its environment, be considered in an explanation of the technique.

Whereas these facts may seem trivial and unimportant to many, anything that seeks to contribute to the absolute truth in science is of value.

177 Walnut Street.

The Spinal Fluid Syndromes of Nonne and Froin and Their Diagnostic Significance.—F. M. Haines concludes that compression of the spinal cord and its meninges from whatever cause leads to the formation of a cul-de-sac more or less complete distal to the site of compression. This leads to characteristic changes in the spinal fluid. The earliest characteristic change has been described by Nonne as an increase of proteid without cell increase. As the condition of cord compression persists, the fluid gradually becomes yellow in color (xanthochromia), the proteid content increases enormously, and the fluid, when removed, coagulates spontaneously (Froin's syndrome). Pleocytosis may or may not be present, depending on whether or not the meninges are inflamed. Xanthochromia must be distinguished from erythrochromia due to hemoglobin staining. The Nonne-Froin syndrome when present always indicates a compression lesion of the cord.—*American Journal of the Medical Sciences.*

Medicolegal Notes.

Liability of Railroad Hospital Association.—In an action by the father of a deceased employee of a railroad company against a hospital association for the neglect of its physicians and attendants in failing to give the son suitable care and attention, it appeared that the defendant was an association maintained by the railroad for the treatment of the employees while sick, and was supported by the monthly contributions of all its employees who, so long as they remained in the service of the company and contributed to the fund, were entitled to the benefits of the hospital free of charge. The Kansas Supreme Court applied the rule that charitable associations conducting hospitals are not liable for the negligence of their physicians and attendants resulting in injury to patients unless it is shown that the association maintaining the hospital has not exercised reasonable care in the employment of its physicians and attendants.—Nicholson v. Atchison, Topeka & Santa Fé Hospital Assn. (Kan.) 155 Pac. 920.

Inference That an Insured Physician Knew of Disease Affecting Him.—The Colorado Supreme Court holds that an insurance company cannot avoid its contract of insurance upon a mere inference that the insured, solely because of the fact that he was himself a physician, knew he was afflicted with a particular disease. To justify such avoidance upon the part of an insurance company, the testimony should so satisfy the mind of the court as to be conclusive in that respect. Northwestern Mut. Life Assn. v. Farnsworth (Colo.) 153 Pac. 699.

Illegal Prescriptions for Intoxicants.—The Missouri statute, Rev. St. 1909, Sec. 5784, declares that any physician who shall make any prescription to any person for intoxicating liquors to be used other than for medicinal purposes shall be deemed guilty of a misdemeanor. Section 5781 provides the character of prescription which will protect a druggist in making sales of intoxicants in quantities of less than four gallons. A physician who unlawfully issued a prescription for intoxicating liquor wrote the prescription in such a manner that the druggist who filled it was not protected. In a prosecution against the physician under section 5784 it was held that nevertheless he was guilty of a violation of that section; the word "prescription" as there used meaning a direction of remedy or remedies for a disease and the manner of using them, and not necessarily a valid prescription which would protect the druggist that filled it. State v. Nicolay (Mo.) 184 S. W. 1183.

Licensing of Chiropractors.—The California statute of 1913, regulating the practice of healing arts, makes any one who shall practice any system of healing, or who shall diagnose, treat, operate for, or prescribe for, any disease, without a license, guilty of a misdemeanor, while section 22 omits persons treating by prayer. A drugless healer, of the class known as chiropractors, contended that the act was discriminatory, as it made greater requirements of such healers than it did of spiritual healers. It was held that the statute was not subject to criticism on the ground that it was discriminatory and lacked uniformity of operation, for a drugless healer who adjusts his patient's anatomy might well injure him, while the prayers of an ignorant person would be of no injury. It was argued that to require no diagnosis from those who profess to treat disease by prayer while prohibiting all other unlicensed persons from diagnosing various ailments is an unjust and unconstitutional regulation, favoring one class of citizens unduly. The court said that those who believe that divine power may be invoked by prayer for the healing of the body believe also that God is all-powerful. Patients receiving their ministrations know this, and therefore no fraud or injury may be practiced upon such persons by reason of any lack of skill by the healers in determining the nature of the diseases to be treated. But those who elect to depend upon some other system of treatment have a right to protection by the State from the ministrations of unskillful, uneducated persons. For example, a sufferer from a fever, who summons a licensed physician holding himself out to the public as one qualified to treat the sick, is entitled to the services of a doctor who has been taught to discriminate between typhoid and smallpox. In other words, the right to practice medicine should carry with it some assurance to the public that the licensed practitioner possesses reasonable proficiency in the technique of his profession.—People v. Jordan, California Supreme Court, 156 Pac. 451.

THE SIGNIFICANCE OF THE APICAL SHADOW IN DENTAL ROENTGENOGRAMS.

ROENTGENOLOGICAL examination of the teeth and jaws, with the interpretation of the roentgenograph, has without question come to be a permanent addition to the methods of detecting possible chronic focal infection as the causative factor in certain cases of systemic disease. It is thus seen that the significance and interpretation of the apical shadow about the apex of a tooth so frequently found in the roentgenogram are of the greatest importance. A brief consideration of this subject is not without interest to every practitoner of medicine.

The dark shadow found around the apex of a tooth means the lessening of density in that particular area, due to decalcification in the bone. Clinically it may result from infection (generally from a dead tooth) or from a blind abscess; and, if cyst and pressure atrophy are excluded, it may mean a devitalized tooth through the apex of which the infection had spread to form an abscess, or a healthy tooth with a blind abscess. In all cases appropriate clinical tests should be employed to determine whether the tooth under investigation is dead or healthy. In some cases a tooth may be proven to be dead by objective tests and subjective symptoms, and still no abnormality may be demonstrable roentgenologically, for the reason that the alveolus may not at all be involved as a result of the infection or the degree of decalcification is insufficient to produce visible changes in the roentgenogram. In fact, subjective symptoms may make their appearance before changes can be detected in the roentgenographic examination.

Mackee and Remer, in an interesting paper on this subject in the *American Journal of Roentgenology* (March, 1916), call attention to the fact that very slight apical shadows should lead to decided care in interpretation, particular consideration being given to the exclusion of anatomical shadows, photographic defects, artifacts, and overlapping shadows. For example, the authors point out that the antrum of Highmore, the foramen of the inferior dental canal, and the nasal cavity may form overlapping shadows in the region of the superior molars, lower bicuspids, and superior central incisors respectively. They insist, however, that a persistent apical shadow, found in a number of radiograms taken from different angles, is most certainly suspicious.

It is true that lack of study of this subject has led to the belief quite common among physicians that an apical shadow means pus and cavity formation in the alveolus. Now, although it is true that a very dense shadow and complete loss of bone detail indicate the presence of a cavity, still, as a general proposition, one must realize that a cavity cannot with positiveness be said to exist in cases in which nothing more than a dark shadow with bone detail is found in the roentgenogram. Mackee and Remer properly assert that an apical shadow does not necessarily mean a cavity or the presence of pus. In fact, pus should not be diagnosed by the roentgenologist but by the dentist. Apical shadow does, however, mean decalcification, which may be from many causes—atrophy or absorption due to prolonged irritation or pressure, acute infection, or the remains of former disease (scar tissue).

It is important to remember that "a shadow can be made lighter or darker, smaller or larger, by varying the exposure, the quality of the ray, the depth of the development, the photographic emulsion, the developer, the angle, etc." When examining the patient roentgenologically for evidence of dental sepsis in cases referred by physicians who suspect it as a cause of systemic disease, the alveoli of both jaws, with the apex of every tooth, should be included in the examination. Conservatism in interpretation should be the rule for the roentgenologist. In every instance the findings of the dentist should be taken in conjunction with those of the roentgenologist.

Ottolengui, in the same journal, directs our attention to the fact that the physician (whether as clinician or roentgenologist) is too frequently apt to label as pathological and declare to be a focus of infection any area which seems to be rarified in the roentgenogram. He makes the following declaration which it would be well for all of us to keep in mind constantly when doing this sort of work: "The radiograph is not a picture of disease. It is a record only of the varying resistance to the passage of the ray offered by the parts pictured. The interpretation of the meaning of these shadows, and a decision as to whether they are caused by pathological conditions or not, require on the part of the radiographic diagnostician a full knowledge of the clinical expressions of the various affections, and of the varying shadows cast in consequence thereof."

SOME PHASES OF ACIDOSIS.

ACIDOSIS is now held to include a good many conditions which formerly were not classified under this head, and in fact it is now believed that acidosis plays a part, sometimes predominant, in the causation, or rather the progress of various diseases and affections. Within the past few years the question has been studied minutely and from several standpoints, and our knowledge in this direction has increased very considerably. Of those who have contributed to the attainment of this knowledge none has been more earnest in his endeavors nor more successful in his results than Cammidge, and it is therefore of interest to find his most recent views on this subject in the special acidosis number of *American Medicine* for June.

Cammidge defined acidosis as a condition in which there is an accumulation of acid products of metabolism in the body owing to an excessive production, or to defective elimination, or to both together, and he goes on to say that it is now generally agreed that the clinical symptoms of acidosis are not dependent upon any specific toxic properties possessed by these metabolic products, but arise from the impoverishment of the body in bases that occurs as a result of the acid character of these products. Thus, considered from the standpoint of a deficiency of bases, the term acidosis may be extended to include conditions in which there is an excessive primary loss of bases, or an inadequate absorption of base-forming substances through the intestinal mucosa to meet the ordinary requirements of the body.

Consequently the possible causes of an absolute or relative acidosis are numerous and to a greater or lesser extent are encountered in a wide variety of conditions. Cammidge confines himself to a consideration of diabetes mellitus in which acidosis assumes the dominant rôle and is often the determining factor in a fatal issue. It is impossible in limited space to recount at length Cammidge's interpretation of acidosis in diabetes mellitus, and it must suffice to say that he points out that as a result of clinical experience a vegetable diet has come to be an important feature of most modern methods of treating diabetes, and that casein has been employed empirically in recent years as the chief constituent of many so-called "diabetic" breads and biscuits. He further points out that a vegetable diet, or at least a system of dieting that contains a large proportion of "vegetable days," has other advantages, not the least of which is the preponderance of base-forming over acid-forming elements that it furnishes.

In the same journal a good deal of attention is paid to that condition of childhood known as cyclic vomiting. Eric Pritchard discusses this phase of acidosis in an original manner, and among the conclusions at which he arrives are that the measure of the severity of an acidosis is not to be estimated on the basis of the amount of acetone or other acid bodies in the urine, but on the degree of carbonate depletion, and that one of the effects on the system is to cause a serious hemolysis. Hence there must be an active regeneration of red blood corpuscles or a profound anemia will result. This is probably the explanation of the enlarged ends of long bones in rickets.

The more chronic effects of acidosis are observed in rickets, cyclic vomiting, recurrent bilious attacks, and the troubles connected with dentition. The treatment, both preventive and remedial, consists in the adjustment of the food to the physiological requirements in each individual case, combined with the administration of alkalies as may be indicated.

There is little doubt that our knowledge of acidosis is very much clearer than formerly, but it may also be said, without much fear of contradiction, that there is yet much to be learned on the subject. While we may be well on the way, we are by no means at our journey's end.

DISEASE IN THE GERMAN ARMY.

Not a great deal of information has filtered through to the outside world from the Central Powers about health conditions in their armies. This is due partly to the iron rings about their troops and the amount of censoring each item of news receives before it reaches America, but partly also to the secretiveness of the German authorities in their handling of military problems. It can hardly be imagined, however, that they deal with the medical problem other than efficiently when we consider their capacity for organization and their scientific attainments.

In one of the last issues of the *Berliner klinische Wochenschrift* which the British censor has allowed us to read, Dr. Goldscheider, who has been in the field with the German army, notes a few of the conditions which he found there. He has some criticism to make of the methods used for transporting the sick which seemed to him to be inadequate. Discussing typhoid fever, he says difficulty was experienced in making an early diagnosis on account of the fact that the bacteriologists were not near enough to the front. He mentions Weil's disease at one point and a few other infectious diseases, but they did not seem to occur in large numbers. Heart trouble appeared to be one of the most serious problems and this corresponds with the experience of the English, who report a condition which has been referred to as the "soldier's heart" by Sir James Barr and has given rise to a great deal of discussion, not devoid of acrimony. Dr. Goldscheider deplores the lack of accuracy in diagnosis of affections of the heart in recruits, the distinction between organic and hemic murmurs and between myocarditis and cardiac neurosis being especially faulty. In fact, he says, a great many soldiers were invalided who should never have been accepted for service.

Dr. Stadelmann, at a meeting of the Berliner Medizinische Gesellschaft, also lays stress on the large number of heart cases; he says that 50 per cent. of all soldiers were neurasthenic and of this number 50 to 70 per cent. complained of heart symptoms while in reality only 5 per cent. had organic heart trouble. These men were formerly removed from the front, given prolonged rest in bed and medication, but they failed to improve under this régime so that now they were kept in convalescent quarters behind the front and given light work to do, their minds being kept off their symptoms. The real trouble with these patients was that they did not want to return to the front.

ANEMIA AND CHLOROPHYLL.

One occasionally sees statements that certain green plants, such as spinach, leeks, etc., have special dietetic value because of an iron content, but so far as we know the claim that chlorophyll, wherever it is found, is a hematopoietic substance, is of recent origin. Professor Bürgi in the *Correspondenz-Blatt für Schweizer Aerzte*, April 16, endeavors to show that the green coloring matter of vegetation is not only the most powerful regenerator of the blood, but a valuable stomachic and regulator of assimilation.

In the same journal for June 3 Maillart of Geneva attempts to demonstrate the same thesis from an economic-historical viewpoint. True chlorosis is notably rare in Geneva, and this may be due to the fact that the town is surrounded by a vast acreage of market gardens. These in turn have been made possible by the great fertility of the land, which has made the industry profitable for centuries. Green herbs are produced in the greatest variety. So much in use are legumes that the Genevese have been termed "legumivores," and legume soup, which also contains leeks, lettuce, and carrots in the winter, and salad vegetables in the summer, is a characteristic Genevese dish which is famous as an appetizer. Aside from the soup, great quantities of green vegetables are consumed: green beans, green peas, watercress, chervil, dandelion greens, artichokes, asparagus, sorrel, spinach, and other chlorophyll-containing vegetables. On the other hand, the demand for vegetables poor in chlorophyll, such as cabbage and cauliflower, is not greater in Geneva than elsewhere in Switzerland. When the Genevese emigrate they invariably miss this abundance of green stuff. Maillart advises the daily use of green legumes, not only for the anemic and dyspeptic, but for the healthy as well. Chlorophyll has been given as such to the anemic, but doubtless cannot replace the fresh vegetables. The author does not allude to the value of tinned beans and peas in this connection, but it is evident that from the dietetic standpoint they cannot replace the fresh articles.

Rubber Tissue Tendon Sheaths.

The old adage "Necessity is the mother of invention" has been exemplified many times during the present European war when lack of time or of materials has forced surgeons to improvise instead of following the beaten track in matters of technique. One instance of this, a device which may be worth utilizing in selected cases in the future, is found in the report by M. Petit of Château-Thierry (*Revue de Chirurgie*, January, 1916) of two cases where the tedious dissection of a fat-fascia flap was avoided by using sterile rubber tissue to prevent tendons from becoming adherent to the skin. In the first case there had been a wound of the forearm which had cicatrized with fusion of the flexor tendons to the skin, bringing about a *main en griffe*. Petit freed the tendons and interposed a rectangle of sterilized rubber tissue. The skin wound was then entirely closed, healing was by first intention and function of the tendons was perfect. Later the sheet of rubber tissue worked out at one portion of the wound but the perfection of the functional result was maintained. In the second case there was adherence of the flexor tendons to the skin of the lower third of the forearm, again with *main en griffe*. The same technique was employed with perfect result in every way; for in this instance not only was function perfect but there has been no evidence that the rubber tissue is to be extruded.

Necessity of Very Prolonged Mercurial Treatment in General Paralysis.

It has generally been understood that a thorough course of mercurial treatment has no permanent value in the treatment of paresis, but something must depend on what is meant by a prolonged treatment. If a cure faithfully kept up for a year be of no avail in one case this does not straightway justify the assumption that another case would not show improvement after two years of exhibition. But to-day we have authorities who mean by prolonged treatment not less than ten years. In a recent number of the *Annales des maladies vénériennes* (May, 1916), Gaucher cites several cases in point. Thus a man contracted syphilis in 1892 and showed the first symptoms of paresis in 1896. He was at once placed on mercurial injections with iodide of potassium inwardly which were maintained year in and year out. For about ten years he remained free from pupillary disturbances and changes in the reflexes. He showed some of the ordinary evidences of constitutional syphilis despite the treatment. The leading symptoms suggestive of paresis were limited to headache, crises of aphasia, vertigo, staggering, diplopia, etc. At the expiration of ten years the psychic-somatic picture of paresis appeared quite suddenly and completely. The mercurial treatment was not in any way modified. Now, 1916, after 20 years of paresis the man still lives, still receives his injections of benzoate of mercury with iodide inwardly. Not all symptoms progress and some of them subside. He is able to take care of himself and his personal affairs. His family no longer wish to have him committed. Years ago such men as Brissaud, Raymond, and Joffroy pronounced the patient incurable. The author looks upon the case as a real cure, although he thinks it unwise to stop the treatment. A parallel case is also related.

News of the Week.

The Poliomyelitis Epidemic.—There were fewer new cases of infantile paralysis reported in this city during the first part of the week than there were in the same period last week, though the deaths had proportionally increased. That the disease is not declining, however, was shown by the fact that the number of new cases (150) reported on Tuesday was greater than on any previous day. Outside of the city the number of cases has increased, a total of 237 cases being reported in New York State from the beginning of the epidemic to July 24, and 274 cases in New Jersey. In this city up to July 26, the total number of cases was 3,260 and of deaths 682.

Great Britain Bans Red Cross Shipments.—The appeal of the American Red Cross that supplies be allowed to be sent from here to Germany has been refused by Great Britain on the ground that they are not needed. In support of this contention, Professor Hochenegg of the medical corps of the Austrian Army is quoted as stating that there is no shortage and no prospect of shortage in medical supplies of any kind or of materials for surgical dressings. The British Government therefore holds that if supplies of rubber and other materials were admitted to Germany it would not conduce to the welfare of the sick and wounded but would merely set free an equal amount of such materials for belligerent purposes.

A Warning to Turkish Hospital Ships.—The Russian Government has given notice that all Turkish hospital ships will be sunk on sight in reprisal for the sinking of the two Russian hospital ships, *Portugal* and *Peryod* by the Turks.

Dr. Charles D. MacCarthy, Jr., of Malden, Mass.,

has received the cross of the Legion of Honor in recognition of his work with the American Ambulance in France.

Sir Victor A. H. Horsley died on July 16 at Amora in Mesopotamia of a heat stroke. He was born in 1857 and was knighted in 1902. He was emeritus professor of clinical surgery and consulting surgeon at the University College Hospital, London. At the outbreak of the war Sir Victor went to France with the Red Cross. Then he accepted a commission as a colonel and went to Egypt as consulting surgeon. Learning of the great need of medical officers in Mesopotamia he requested to be transferred and reached the Tigris last March.

An Army Hospital Train.—A hospital train of ten Pullman cars, designed by the Army Medical Department is in course of construction. Five of the cars are to be equipped with regular hospital beds and have large side doors for loading and unloading stretchers, two will be of the regulation sleeper type, equipped with extra fans, medical cabinets, and ice tanks, one will carry a complete operating room, and another a kitchen large enough to care for over 200 sick. In addition to the regular army personnel, the train will carry a special corps of army nurses to serve in the wards and operating car. The train will be painted maroon, with the insignia of the Army Medical Department.

Army Hospitals on the Texas Border.—Secretary of War Baker announces that the Department is constructing a number of small hospitals at minor posts along the border with base hospitals at Fort Sam Houston and Fort Bliss, Texas. Base hospitals have been authorized and are now being completed, supplied with personnel and equipment, at Brownsville, Eagle Pass, Laredo, Nogales, and Fort Crockett. There are seven field hospitals with the troops on the border, each having a capacity of 216 beds. This does not include the field hospitals of the organized militia now on the border.

Medical Care for Soldiers' Families.—A number of Detroit physicians have volunteered to give medical service free, in case of need, to the families of the members of the National Guard who have been sent to Texas.

Psychological Laboratory at Bellevue.—A psychological laboratory has recently been established at Bellevue Hospital, in New York City, under the direction of Dr. Menas S. Gregory, chief of the Psychopathic and Alcoholic Services. Facilities will be provided for both clinical and research work. As these services admit about 15,000 patients annually, the opportunities for research will be exceptional. Dr. Leta S. Hollingworth, formerly psychologist in the Department of Public Charities in New York City, has been placed in charge of the laboratory.

A Two-Year Pre-Medical Course.—A bill has been introduced in the Georgia Legislature requiring a college course of two years as a preliminary for admission to any medical school in the State. The bill also provides that there shall be no appeal from the decision of the Board of Medical Examiners when the license of a physician is revoked.

Rockefeller Institute.—Dr. Alphonse R. Dochez, hitherto an Associate in Medicine has been made an Associate Member. Dr. Henry T. Chickering has been appointed Resident Physician in the Hospital to succeed Dr. Dochez. The following have been made Associates: Dr. Louise Pearce (Pathology and Bacteriology); Dr. Frederick L. Gates (Pathology and Bacteriology). The following have been made Assistants: Dr. Oswald Robertson (Pathology and Bacteriology), Mr. Ernest Wildman (Chemistry). The following new appointments have been made: Dr. Rhoda Erdmann, Associate in the Department of Animal Pathology; Dr. Rufus A. Morrison, Assistant in Medicine and Assistant Resident Physician; Dr. John Northrop, Assistant in the Department of Experimental Biology; Dr. Jean Oliver, Assistant in the Department of Pathology and Bacteriology; Dr. Ernest W. Smillie, Fellow in the Department of Animal Pathology; Dr. William D. Witherbee, Assistant.

Dr. A. A. Eisenberg, formerly pathological anatomist in the U. S. Army Medical Museum and School, Washington, D. C., has been appointed pathologist at Charity Hospital, Cleveland.

A Memorial to Major Walter Reed.—It is planned to erect a memorial to the late Major Walter Reed, head of the Army Commission which confirmed Finlay's mosquito theory of the transmission of yellow fever, on the campus of the University of Virginia, of which he was a graduate.

Dr. James A. Lyon, assistant Superintendent of the Rutland, Vt., State Sanatorium, who recently entered the service of the government in the 2d ambulance company, was the recipient, in leaving for the front, of a loving cup from the patients of the institution.

Vehement Vegetarianism.—An ardent advocate of the moral and hygienic beauties of vegetarianism, who has been arrested eighteen times for creating a disturbance by his uncontrolled enthusiasm in the cause, was sentenced in a police court in this city the other day to a two year term in the workhouse for attacking a woman who was coming from a butcher shop.

The Broad Street Hospital.—The trustees of this institution have bought a plot at the corner of Broad and South Streets, New York, as the site for a new hospital. The building with 100 beds will be ready for occupancy in the autumn.

A Psychopathic Clinic at Sing Sing.—Warden Osborne announced recently that a psychopathic clinic under the direction of Dr. Bernard Glueck has been established at Sing Sing Prison. The object of the clinic is not only to determine the mental status of the present and future inmates of that institution, but also to inaugurate a study of the underlying causes of crime along the lines suggested at a meeting of the New York Academy of Medicine held last winter. The Rockefeller Foundation has contributed the necessary funds for the clinic. Dr. Glueck, who will be appointed resident psychiatrist, was formerly on the staff of the Government Hospital for the Insane at Washington. The general supervision of the work will be under an Advisory Board consisting of Drs. August Hoch, William Mabon, William L. Russell, George H. Kirby, L. Pierce Clark, and Thomas W. Salmon.

Obituary Notes.—Dr. WILLIAM EVANS CASSELBERRY of Chicago died at his home in Lake Forest on July 11. He was born in 1858, and was graduated in medicine from the University of Pennsylvania in 1879. He began practice in Chicago in 1883. He was professor of laryngology at the Northwestern Medical College and laryngologist to St. Luke's Hospital. He was a member of the Chicago Academy of Science, the National Association for the Study of Tuberculosis, the American Academy of Ophthalmology and Oto-Laryngology, the American Laryngological Association, the Chicago

Laryngological and Otological Society, the Illinois State Medical Society and the American Medical Association.

Dr. SAMUEL D. BOOTH of Oxford, N. C., died on June 29 at the age of 75 years. He was a graduate of the Medical College of Virginia, Richmond, in 1867.

Dr. ROSCOE SMITH of Auburn, Me., died on July 8 at the age of 80 years. He was born at Peru, Me., and was graduated from the Harvard Medical School in the class of 1870. The following year he began practice in Turner, living there until 1889, when he retired, and five years later moved to Auburn.

Dr. JOHN P. CORRIGAN, for over 25 years a practicing physician in Pawtucket, R. I., died in Washington, D. C., on July 6, of ptomaine poisoning. He was born in Ireland in 1856, and was a graduate of the Bellevue Hospital Medical College, New York City. He had recently retired from medical practice and was about to be received into the Order of St. Dominick, having just completed his novitiate.

Dr. JOSEPH W. HENRY of San Francisco died in San Jose on June 28 at the age of 47 years. He was born in Ireland, and was a graduate of the Medical Department of the University of Southern California in the class of 1897.

Dr. HARRY CARTER of Manchester, N. H., died in the Hartford (Conn.) Hospital on July 4 at the age of 40 years. He had for many years been engaged as surgeon in the mercantile marine, and had had several very trying experiences, including shipwreck and fire at sea.

Dr. S. G. POPPLEWELL of Milo, Mo., died of cancer of the stomach on July 5 at the age of 69 years. He was a graduate of the College of Physicians and Surgeons, Keokuk, Iowa, in the class of 1876.

Dr. ARTHUR CLEVELAND COTTON of Chicago died of heart disease on July 12 at the age of 69 years. He was born in Grieggsville, Ill., and was graduated from Rush Medical College, Chicago, in 1878. He was pediatrist to the Presbyterian Hospital and professor of pediatrics in Rush Medical College. He was a member of the Chicago Medical Society, the Chicago Pediatric Society, the Chicago Medical Examiners' Association, the American Pediatric Society, the Illinois State Medical Society, and the American Medical Association.

Dr. CHARLES HAMILTON HUGHES of St. Louis, for many years editor of the *Alienist and Neurologist*, and professor of nervous diseases in the Barnes Medical College, died on July 13 at the age of 77 years. He was born in St. Louis, and was graduated from the Washington University Medical School in 1859. For a short time after graduation he served in the Marine Hospital Service, and then began practice in Warren County, Mo. He served as surgeon in the Federal Army during the Civil War, and at its close became superintendent of the Missouri Asylum for the Insane at Fulton. In 1871 he began practice in St. Louis and soon acquired a wide reputation as a neurologist and alienist. He was no "brain-storm" theorist, but held in many of the murder trials in which he gave expert testimony that the murderer was sane enough to be responsible for his acts.

Dr. EDWARD N. FLYNN of Jeffersonville, Ind., died of Bright's disease on July 9 at the age of 49 years. He was born in New Bedford, Mass., and was graduated from the Louisville Medical College in 1897. He served for four years as mayor of Jeffersonville.

Correspondence.

INTRASPINAL INJECTION OF ADRENALIN CHLORIDE IN ANTERIOR POLIOMYELITIS.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—I desire to present the following brief report regarding the use of adrenalin chloride, intraspinally, as suggested by Dr. S. J. Meltzer in the treatment of infantile paralysis at the New York Throat, Nose and Lung Hospital. There are 51 cases under my observation at the present time. It is unnecessary to give in detail the routine treatment other than that of the adrenalin injections. All the patients received urotropin in moderate doses.

Not knowing the dose of adrenalin in these conditions I began the injection of 3 minims of a 1-1000 solution, but soon increased the dose to 30 minims without any deleterious results. The injections are given every six hours as a routine. The reaction upon the part of the patient from the procedure is practically unnoticeable except that in a few cases where a high intraspinal pressure has been relieved before the injection of adrenalin, headache and vomiting may follow. These phenomena are probably due to the sudden relief of the high intraspinal tension and not to any action of the adrenalin. From a clinical point of view, it is well to state that a vast majority of all the cases have a notable increase of intraspinal pressure. Usually the spinal fluid is allowed to run off through the needle, but in some cases I have drawn off with the syringe from 1 to 15 c.c. It is noted that the intraspinal tension decreases as the injections are continued.

I would not advise the use of adrenalin in larger doses than 2 c.c. since pulmonary edema may be produced by large doses of the drug. However, the slow absorption from the spinal canal will allow the injection of large doses without any deleterious results.

As to the physiological action of adrenalin in these conditions further work must be done, for up to the present the explanation of its action is only theoretical. In the cases where voluntary movement of various parts of the body was lost for a period of time and regained, the loss could not have been due to any degenerative changes in the neurons from pathological lesions. The probability is that the path of the lower motor neurons in the spinal canal was blocked from pressure caused by the exudate produced at the area of inflammation which is in the neighborhood of the ventral horns of the gray matter of the cord, thereby disturbing the continuity of the reflex arc and the free passage of impulses from the upper motor neurons. It has been shown experimentally that adrenalin will relieve, to a marked degree pressure around an inflammatory area and reduce the focus of inflammation. Should the motor disturbance in infantile paralysis be due to pressure, then intraspinal injections of adrenalin given before there are degenerative lesions in the nerve tissue might well produce beneficial results in progressive malady impeded.

The following cases are reported that some idea may be gained as to the condition of the patients before and after the injection of adrenalin. Several other cases showing equally gratifying results are under observation.

CASE I.—J. K., male, aged three years. Admitted to the hospital July 15, 1916. General condition very low.

Unable to swallow food or drink; extremities cold; absence of radial pulse; heart block of a 5-4 rhythm; auricular fibrillation at times; respirations slow and principally diaphragmatic. No voluntary motion of limbs; legs flexed upon the thighs; absence of all skin and tendon reflexes. Hyperextension of spine. July 22: Patient raises himself up in bed; good control of all voluntary muscles; respirations normal; normal rigidity of spine, and force and rhythm of heart excellent. All skin reflexes present except the left plantar. Right knee jerk and both elbow tendon reflexes present.

Case II.—S. D., male, aged five years. Admitted to the hospital July 15, 1916, in a very restless condition. Marked hyperextension of spine; unable to move either the left arm or right leg; complained of severe pain in back and lower extremities. All the skin and tendon reflexes absent. July 22: Normal flexion and rigidity of spine; able to flex, extend, and move the left arm in any direction; raises right leg about 6 inches off the bed; all skin reflexes present except the plantar. Right knee jerk present.

Case III.—J. L., male, aged three years. Admitted July 14, 1916, in a very stupid condition. Entire musculature in a marked state of hypotonicity; no voluntary motion; absence of both skin and tendon reflexes. Sensation of pain hyperacute. July 22: Muscular tone much improved; very good flexion and extension of both arms and left leg; right leg is in a passive state. Both plantar and cremasteric reflexes present. Left knee jerk present.

In each of the above cases adrenalin was administered in doses of 2 c.c. every six hours.

P. M. Lewis, M.D.
House Surgeon.

New York Throat, Nose, and Lung Hospital.

TREATMENT OF INFANTILE PARALYSIS.

To the Editor of the Medical Record:

Sir:—The paper of Dr. Meltzer in the issue of the Medical Record for July 22 emboldens me to publish a suggestion I made a week ago by telegraph to Surgeon General Blue, Commissioner Emerson, and a prominent neurologist in Brooklyn. The first referred the matter to his representative in New York, Dr. Lavinder, who has written that he would give attention to the matter so soon as his work was organized.

I ask a modicum of space to call further attention to the matter. In the February report of the Hygienic Laboratorq, Atherton Sidell published some remarkable data on polyneuritis of pigeons that had been fed on polished rice that may give a valuable clue to the treatment of poliomyelitis, despite the fact that the pathological lesions are quite different. Therapeutics is, after all, but empirical; our most valued drugs like quinine and digitalis having been discovered and successfully used before their rationale was known. Dr. Meltzer's probable rationale of the action of adrenalin in poliomyelitis may be applicable to my suggestion for its therapy derived from Sidell's experiments, who found that pigeons suffering from induced polyneuritis are in an hour relieved from paralysis and entirely restored to health within twenty-four hours, also that pigeons fed with polished rice for the purpose of producing polyneuritis do not contract the disease at all if at the same time given 1 c.c. of a waste product derived from brewers' yeast.

Would not a trial of this agent be demanded in view of the utter helplessness under which the physician now labors? Sidell claims that this waste material of breweries may be concentrated so that 5 grams would suffice for a man. The quantity for a child may be calculated in the usual way. In view of the fact that the preparation is odorless, almost tasteless, and harmless, the experiment is worth trying.

Simon Baruch, M.D.

Long Branch, N. J.

TYPHOID VACCINE IN POLIOMYELITIS.

To the Editor of The Medical Record:

Sir:—In a recent number of the *Journal A. M. A.* appeared an article by Drs. Miller and Lusk on the treatment of arthritis by the injection of foreign protein (see Medical Record, June 17, page 1100), in which the authors advocate the use of typhoid vaccine intravenously. I can speak well of this non-specific treatment of arthritis, and from personal trial and observation can endorse its use in infectious arthritis. It must be given cautiously and carefully in selected cases. It produces a violent reaction, and in some cases an increase of pain in all the affected joints temporarily. Mention is made in the article of the experiments of Vaughan, whereby a certain amount of immunity against specific infections by non-specific bacteria was obtained. Animals were immunized against typhoid and cholera by dead cultures of *B. prodigiosus* and *B. subtilis*. A moderate and transitory immunity against colon infection was obtained by injecting egg albumin into animals. Many years ago Klein in England immunized animals against *B. pyocyaneus* infection by using killed cultures of *B. prodigiosus*. In view of the widespread epidemic of poliomyelitis in the East, with the mode of infection as yet undiscovered and with a mortality rate of 20 per cent., it seems that some non-specific immunizing measures might at least be experimented with. By immunizing children with typhoid vaccine, typhoid fever can be prevented, and it is possible that by the various antibodies thus mobilized another bacillary infection may be prevented or defeated.

The two schools, that of Ehrlich and of Bordet, long contended as to the specficity of antibodies, Bordet and Metchnikoff holding that there was but one, the substance sensibilitrice. Leucocytosis is produced by injections of typhoid bacilli, and antibodies also; the natural defenses of the body might overflow and destroy the bacilli of anterior poliomyelitis. It would be interesting to learn if anybody who had recently been immunized by vaccines of any sort, but particularly typhoid vaccine, developed poliomyelitis. It seems that the procedure can do very little harm, and it might do a great deal of good.

Robert L. Pitfield, M.D.

Germantown, Pa.

A HANDY BANDAGE ROLLER.

To the Editor of the Medical Record:

Sir:—Apropos of a suggestion in a recent editorial article in the Medical Record, the following description of a handy bandage roller, made in an emergency at the home of a patient, may be serviceable to others under similar circumstances.

My patient had a brawny swelling of the breast about two weeks after a difficult labor. The same breast had been badly riddled by a deep abscess after her other child was born, and it seemed as if an abscess was now inevitable. It was in March, 1885, and I had just been reading the valuable contributions of Dr. Philander A. Harris of New Jersey to the *American Journal of Obstetrics*, upon the treatment of mammitis by bandaging and rest, and I determined to use the long, wide bandage over a cotton compress, as he had recommended. But this called for a bandage at least 15 or 20 yards in length and about 3 inches wide. We made it from six or seven lengths of a sheet, lapped and stitched to-

gether, and to wind it I extemporized a crank and spindle from an umbrella rod with its brace attached, that met my eye, simply bending the slim, square brace, near the outer end of it, at a right angle, and leaving 2 or 3 inches of the rod still attached to serve for a handle.

A stout little salt-box—3 x 4 x 9 inches—with two holes at each side, very near together, at one end to receive two short pieces of the rod, and other holes near the other end to receive the crank shaft, and the machine was ready for use. The bandage was passed over the end of the box, under the first rod, over the other and then to the crank, and by moistening the end of it slightly and pinching it snugly to the crank shaft, while the first few turns were made, our bandage was quickly and firmly wound. The wrinkles in the cloth were smoothed out as they passed by the rod at the end of the box, and pressure or traction there, as the bandage was fed into the machine, made the bandage, when finished, as firm and hard as might be desired.

The improvised machine worked so well I brought it home, smoothed the edges and rough places, had the whole thing enameled in black, and have used it and Dr. Harris's long bandage from time to time ever since, and both of them always with satisfaction. C. H. L.

SARATOGA SPRINGS FOR CARDIOVASCULAR DISEASES.

To the Editor of The Medical Record:

Sir:—In the interest of sufferers from organic heart diseases who cannot avail themselves of the unique waters of Nauheim, which have made that resort the Mecca of these unfortunates, I desire to comment upon your editorial on this subject in your issue of June 3, and upon the letter of the officers of the Saratoga Springs Medical Society, published July 1, which opposes the accepted views of heart specialists and eminent internists the world over. The officers of this society have by resolution stated "their deliberate and emphatic conviction that for series of successive CO_2 baths given systematically our natural Saratoga Springs mineral water, etc., is fully efficient," meaning, of course, in cardiac cases in which alone such series are prescribed. And our colleagues display commendable catholicity and courtesy by adding, "and further, that it should be used for such series of baths without addition of any salts, *unless* such additions are plainly ordered in the prescription of the physician."

Whether the American profession will be guided by this resolution of a small number of colleagues whose unpublished observations extending over a brief period of a few months in a resort that is still in its infancy so far as CO_2 baths for cardiac disease are concerned, or by the published observations of physicians and eminent specialists all over the world extending over a period of twenty-five years on a material of over a million recorded baths for heart cases alone, is not for me to point out.

I desire to call attention to the fact that the officers of this society have written: "The physicians of Saratoga Springs decry most sincerely the adulteration of these waters for bathing purposes—except when made on special prescription." The Century dictionary define "adulteration" to be "the debasing by substitution of an inferior article for the genuine." Surely they would not suggest such a thing to their colleagues or permit them to do it!

The zeal of the Saratoga physicians for purism is commendable, in view of the real adulteration of the famous drinking waters of that spa long ago abandoned. But this does not in the least apply to these waters for bathing purposes, which have not yet established a reputation by reason of their very early youth. In fact, the publication of two cases is all the literature I could find upon these baths contributed by a Saratoga practitioner outside of propaganda by an official of the reservation in the shape of papers with lantern slides. The paper of Dr. Baruch in your issue of June 17 is really the first rational explanation of the action of the salines in the Nauheim bath, since he has fortified the opinions established on reliable clinical evidence by physiological data and chemical experiment.

It is now clearly demonstrated that the temperature, which is the chief element (according to Groedel and others) in the Nauheim bath, is made bearable and effective for the depreciated heart patient by supersaturation of the water with CO_2; that the CO_2, locally and by absorption, enhances cardiac tone; that the salines facilitate absorption and prevent loss of CO_2 from the water; that CO_2 is the normal stimulant of the respiration, and that this combination of demonstrated physiological actions trains the insufficient heart to better function and prevents lethal complications.

Dr. Baruch gave the reasons of the superiority of the natural CO_2 water over the artificial, and demonstrated clearly that the Saratoga CO_2 waters combined with the calcium and sodium chloride, which are equal in therapeutic effect to the natural chemicals, offers the closest possible approximation to the far-famed Nauheim waters. It is therefore fortunate that we have the opportunity to send our chronic heart cases to Saratoga Springs.

For all other purposes the natural CO_2 Saratoga water is fully effective. I agree with Dr. Baruch's conclusion that no plain CO_2 bath can with advantage be substituted for the natural CO_2 water when combined with the salines in the treatment of cardiovascular insufficiency. This fact is so well recognized in Europe that in resorts having fine CO_2 water, *e.g.* Kissingen, the waters are always reinforced by salines in baths for cardiovascular diseases. I agree with our Saratoga colleagues in their preference for the term Saratoga CO_2 mineral baths, and in the abolition of the term Nauheim baths in prescriptions. Any additions should, as they very properly insist, "be plainly and explicitly ordered in the prescription of the physician."

OUR LONDON LETTER.

(From Our Regular Correspondent.)

OPHTHALMOLOGICAL NOTES—PITUITARY TUMORS—TYPHUS IN CAMP OF PRISONERS OF WAR IN GERMANY—DESERTION OF DUTY BY GERMAN SURGEONS.

London, July 1, 1916.

In the section of ophthalmology (R. S. M.) last week, Dr. F. R. Yelland showed a case of visual orientation, following a wound of four months duration, which was first perceived soon after an epileptic fit. The patient had been improving recently after having had right hemiplegia and erroneous visual projection. A similar case was reported to the B. M. A. last March. Mr. Paton had carried out certain tests on the present case which satis-

fied him that the faulty projection was not due to defective eye movements, but rather to complete destruction of the right occipital cortex, the left being but slightly affected. It looked as if there had been complete severance of the superior longitudinal commisural fibers. Afterward a case of "retinitis pigmentosa" of an unusual character was shown by Captain Carruthers in a young man who had been a soldier for three months. He came under notice as he could not see to drive on the approach of dusk. A younger brother and an elder sister had suffered from night-blindness. Comments were made on the case by the president and several members. A giant perimeter was shown by Captain Hudson, who invited suggestions for improving it; some were offered by Lieut.-Colonel R. H. Elliot, who related some experience he had had with an instrument of his own make.

Dr. A. S. Cobbledeik read a paper on four cases of pituitary tumor, all in women, three of them over 60 years old. The first showed contraction of the visual field, 10 to 20 degrees in extent, and a scotoma for color upward and outward from the central fixation point. This troubled her in reading, and people's faces seemed tinged with blue. There was contraction in the temporal half of the field. Later drowsiness with violent headaches came on with Cheyne-Stokes breathing, but the pupils were not affected. The urine was normal. At the post-mortem examination a pituitary tumor as large as a walnut was found, which Dr. Buzzard regarded as a cyst. Gland-substance enough remained to ensure normal metabolism during the sixty-three years the symptoms lasted. In the second case there was right homonymous hemianopia and myxedema. Memory had begun to fail and speech was indistinct. There was lesion of the left optic tract, probably due to pituitary growth. Thyroid extract was given and there was some improvement of memory and also of numbness which had been present. The discs seemed normal. Little change was noticed in the patient's condition for three years, but after that there was rapid deterioration of vision; the nervous state increased, vertigo and flickerings before the eyes were complained of. The face and hands swelled and later the symptoms were in some degree like Menière's disease, but without deafness or sickness. In the third case there was optic atrophy, obesity, myxedema and diabetes. The sight had been deteriorating for four years, and in the last year drowsiness was on the increase. No tendency to hemianopia. Skiagrams showed enlarged and lobulated *sella turcica*. The fourth case was diagnosed as early optic atrophy, myxedema, and pituitary tumor. There was defective memory, falling hair, suffocating feelings, and heart attacks. A year ago life was despaired of. The discs were normal, but vision for white contracted in every direction.

You have probably some information as to the epidemic of typhus in the camp of the British prisoners of war in Germany. We had a committee of six surgeons sent over to take up duties which had been abandoned by the German surgeons-in-charge. This abandonment seems almost incredible, so contrary is it to the practice of the profession in all countries—Germany included. But on this occasion the desertion of duty was only part of the offence. For these German surgeons not only stayed away from the camp, but made no effort to secure a supply of medical necessaries for their deserted patients. When asked for such by British surgeons on the spot, the answer was insult to the "English swine." We may hope these men were exceptional, but it is a matter of surprise that so far such conduct has not brought condemnation from their professional brethren in their own country.

6. Acute Arthritis Experimentally Produced by Intravenous Injection of the Staphylococcus Pyogenes. E. C. Steinharter.

1. Certain Occupations as Contributing Factors to Diseases of the Skin.—Charles H. White mentions some 46 or more diseases of the skin apportioned among approximately 120 different occupations. He says that he has personally treated all but one of these diseases and has treated in all probability representatives of a very large proportion of the many occupations. He warns against the assumption that these diseases fall to the lot of all men and women who engage in these multifarious pursuits. There are no available statistics covering the whole subject of occupational skin diseases, but in the case of eczema we have more or less reliable figures. The writer cites a number of observers who practically agree that about one-fourth of all the cases of eczema which they treat are directly attributable to the occupation of the patient, and asks the question: "Granted, therefore, that a certain proportion of the community is susceptible to the dangers inherent in its chosen occupation, can anything be done to mitigate or abolish these dangers?" This he answers strongly in the affirmative and believes the desired end may be accomplished by the education of the employer and the employed. Physicians who spend their lives among contagious and often dangerous diseases are fortunately usually spared from sharing the fate of their patients, mainly because of their knowledge of self-protection, and this same knowledge must be disseminated among all classes of human beings. He believes it will not be as difficult a task to educate the employer as many think, since it is not for his interest in any way to have his men incapacitated.

4. A Statistical Study of the Mortality from Diabetes Mellitus in Boston from 1895 to 1913, with Special Reference to Its Occurrence Among Jews.—H. Morrison finds that during the period of 1895 to 1913 there were in Boston 1775 deaths from diabetes mellitus out of a total of 229,468 deaths. In Boston, as elsewhere, there has been a steady rise in the death rate from this disease; it was 7.1 per 100,000 in 1895 and 21.3 in 1913, or 3.1 per 1000 total deaths in 1895, and 13.3 in 1913. The death rate from diabetes has been relatively very high among Jews in Boston, occurring about two and one-half times as frequently among Jews as among their neighbors. A similar analysis shows that the death rate from this cause was very high among those of German, English, and American parentage, so that death from this disease occurred about two times as frequently among them as through the community in general. The largest number of deaths from diabetes occurred among those of Irish parentage, 656 out of 1775, or more than one-third of the total. This death rate, however, was not out of proportion to their population. There were only 11

deaths from diabetes among negroes in Boston from 1895 to 1913. This series of 1775 deaths from diabetes was made up of 958 females as against 817 males. This is contrary to the general observation that diabetes occurs more frequently in the male sex. The largest number of deaths occurred among persons of the seventh decade. The duration of this disease could not be estimated from this study, for nearly half the death returns did not answer at all this question or gave it in indefinite terms. This is a point to be borne in mind in making out death certificates. The author believes the reason for this increase in the death rate from diabetes mellitus is due to the increasing complexity of civilization. It is particularly prevalent among Jews, not because of ethnic peculiarities, but because a severe environment during many centuries has developed a nervous type easily thrown out of balance.

6. Acute Arthritis Experimentally Produced by Intravenous Injection of the Staphylococcus Pyogenes.—Edgar C. Steinharter recalls that he has previously pointed out that the staphylococcus organism of shifting grades of virulence localized on intravenous inoculation in different structures of the body, and within certain limits a selective localization of this microorganism for special organs could be developed by cultivation of the organism in functionating tissue. He has also shown that when the staphylococcus attains an affinity for a certain structure of the body, a fresh subculture of the organism obtained from a focus of infection was apt to possess properties leading to its localization in that tissue. The strain used in the experiments now reported was the one used in the gastric ulcer series. It was obtained from blood culture in a case of septicemia in man. Following the intravenous injection of the organism into the general circulation of rabbits, the joints showed no gross pathological changes except a very occasional slight hyperemia of the periarticular tissues. However, cultures of the apparently negative joints very often yielded a pure growth of the staphylococcus. Further experiments showed that with a more virulent strain of the staphylococcus it localized in the joints and produced typical lesions of arthritis. The organism recovered from the arthritic joints had a tendency to again localize in joints. In some cases the arthritis was the only lesion found at autopsy, but in other cases it was associated with one or more other lesions, namely, duodenal ulcer, appendicitis, cholecystitis, myocarditis, pericarditis, endocarditis, nephritis, colitis, and myositis. The results of localization obtained in connection with the studies of staphylococci are singularly suggestive of Rosenow's experiments with the streptococci. If these facts apply in these cases of streptococci and staphylococci, it would seem possible that they may apply to still other organisms, for so far as we can determine, the essential factor governing localization is growth in the tissue. After an organism has grown in a certain environment, it tends in later generations to select that environment, or at least, to thrive best in that environment.

9. Mayer's Solution. A Noncaustic Hypochlorite. Douglas H. Stewart.

1. Syphilis of the Nervous System.—Eugene D. Bondurant claims that one in five of the inhabitants of the United States has the taint of syphilis in his blood, and that one in five of those who contract syphilis receives some material injury to the nervous system therefrom. One in five of the patients in our insane asylums is placed there by syphilis, this disease ranking first as a cause of insanity. Most of the organic nervous disease met with in practice is a result of syphilis. As a contribution toward facilitating the recognition of involvement of the nervous system in the syphilitic process in its early as well as late stage, he reminds his readers of the following: The neurasthenia syndrome is often present as the earliest evidence of cerebral or meningeal syphilis involving the convexity. The psychasthenic syndrome likewise gives early warning of a diffuse syphilis cerebri affecting the vertex. The occurrence of either of these forms of neurosis in one who has had syphilis indicates danger of subsequent general paresis. Ptosis and other oculomotor palsies are usually diagnostic of meningeal syphilis of the base. Most atrophy of the optic nerve is syphilitic in etiology. Many headaches and neuralgias are caused by syphilis. Most of the pupillary light reflex abnormalities seen are of syphilitic etiology. Chronic neuritis of sensory type is usually syphilitic. Symptoms of spinal sensory root irritation—stabbing pains, anesthesia, disorder of position sense, delay in rate of transmission of nervous impulses, etc., are usually symptoms of syphilitic disease. The onset of epilepsy after the age of thirty-five years means a syphilitic infection. The occurrence of arteriosclerosis, cerebral hemorrhage, softening, etc., before the age of thirty-five years, is seen only in those previously infected by syphilis. Nearly all spastic paralysis is syphilitic in origin. Nearly all disturbances in gait are due to syphilis. Most aphasias and other speech defects in adults are due to syphilis. Most of the abnormalities of the deep reflexes, with the exception of those seen in acute non-specific infectious diseases, are evidences of syphilis. A large percentage of the cases of acute and chronic mental diseases are primarily syphilitic in causation. Syphilis of the nervous system is in its early stages curable by any and all measures which will cure syphilis. In its later stages, after the death of the nerve cells, it is incurable by any means whatsoever.

2. Vertigo and Seasickness, Their Relation to the Ear.—Lewis Fisher and Isaac H. Jones state that all vertigo of whatever cause, be it from stomach, kidneys, eyes, or what not, is directly due to a disturbance along some part of the vestibular paths. It should be borne in mind that the static labyrinths always act in unison. They continuously keep sending out an equal flow of tonic impulses to the whole body. When, however, a pathological process impairs or exaggerates the action of one of the labyrinths, there results a definite disturbance of this nicely adjusted mechanism with vertigo as a symptom. Impairment or stimulation of both sides to exactly the same extent produces no vertigo whatever. Seasickness is therefore an ear phenomenon, by which is meant that the end organ of equilibrium, namely, the static labyrinth, is disturbed by the unaccustomed movement of the boat or ship. Disturbances of the vestibular apparatus can be definitely analyzed by means of the new ear tests. Cases of vertigo, therefore, need no longer be regarded as vague or mysterious, but should be cleared up by means of these ear tests.

4. Tubal Sterilization. Pregnancy Following Bilateral Salpingectomy: A Report of Two Cases and a Complete Review of the Literature.—Alfred Heineberg

reports two cases in which this unexpected sequel emphasized the fact that if sterility had been the object sought by the operations in these cases they would have been classed as failures. He says that pregnancy has unexpectedly occurred in many patients after operations upon the Fallopian tubes performed for the express purpose of producing sterility and in others who were subjected to bilateral salpingectomy for the relief of tubal disease. He gives a résumé of the literature of the clinical and experimental experience with tubal sterilization from which he finds that one may fairly arrive at the following conclusions: 1. There is no method of tubal sterilization which affords absolute security against conception. 2. Simple ligation of the Fallopian tubes with either single or double ligatures has been followed by the largest number of reported failures. 3. Excision of a wedge-shaped section from each cornu of the uterus, followed by careful closure of the opening with musculomuscular and seroserous sutures has yielded better results than any other method. 4. In the light of our present knowledge it seems unwise to advocate any other method than cornual resection. These conclusions are in accord with those arrived at in previous reviews of this subject by Charles (56), Geissler (57), Günther (58), Mironow (59), Offergeld (60), Perdrizet (61), Pestalozza (62), and Sarwey (63.

8. Connellan-King Diplococcus Infection of the Tonsils.—James Joseph King has observed about 100 cases of arthritis at the Hospital for the Ruptured and Crippled in New York from which he concludes that every case of septic arthritis, commonly called rheumatism, is caused by a focus of infection somewhere in the body. It may be found in the tonsils, ears, accessory sinuses, gastroenteric tract, genitourinary tract, and in and around the teeth. The most frequent focus is found in the mouth and the tonsils. A very simple tonsillitis may be followed by complications such as nephritis, endocarditis, myocarditis, arthritis, so serious as to endanger life. The infection may become latent and produce serious trouble weeks or months later at a point far removed from its original site. Where the focus of infection in arthritis exists in the tonsil, the treatment should consist of autogenous vaccines until all infection is cleared up and then the removal of the tonsils by enucleation. In the Connellan-King diplococci infections the blood changes seem to be a simple anemia and in a few cases a slight increase in the number of eosinophiles, four to six per cent. In some cases symptoms other than those for which treatment was instituted have disappeared. For instance, in one patient with arthritis and marked ethmoiditis the culture was obtained from the throat. After two weeks of treatment the arthritis was only slightly improved, but the ethmoiditis and pus in the nose had entirely disappeared. The essayist has found the vaccines eminently satisfactory in a high percentage of the cases treated.

1. Pityriasis Lichenoides Chronica.—Fred Wise presents a clinical and microscopical study of a case mistaken for lichen planus. The eruption exhibited by this patient so closely resembled a widespread lichen planus that a number of dermatologists, even after careful scrutiny, held the opinion that it was, indeed, an unusual example of that dermatosis. The localization and distribution of the lesions, their color, consistence, burnished surface, configuration, occasional grouping and linear arrangement, together with the fact that the patient complained of considerable itching of the affected skin, were determining factors in the diagnosis. There were, however, certain points of departure from the typical picture presented by a disseminated eruption of lichen planus. The papules, instead of being predominantly polygonal, were for the most part oval and round in outline; umbilication was seen in only a small proportion of the lesions, most of them presenting a smooth, glistening surface, without a trace of delling; the fine, whitish, adherent, linear scaling—Wickham's striæ—so characteristic of lichen planus papules, were lacking. Finally, the absence of lingual and buccal mucous-membrane lesions, in a case presenting an eruption so extensive in its distribution, contributed an added element of doubt to the diagnosis of lichen planus. (In Werther's case, however, the buccal mucosæ were affected by the disease.) From the histological standpoint, the minute structure was seen at a glance to be quite different from the characteristic picture of lichen planus, and to conform to that which, when correlated with the clinical appearances, left no other diagnosis open for consideration than that of parapsoriasis. It is well known that the microscopical changes in this group of affections are by no means pathognomonic, in the same sense that the histopathology of lichen planus is pathognomonic, for the various pathological alterations peculiar to parapsoriasis may also obtain in many other cutaneous diseases, or may at least play a minor part in the general morbid process of other dermatoses. A diagnosis of parapsoriasis based on the microscopical findings alone is considered to be, as pointed out by Arndt, a rather uncertain procedure, and should be made with circumspection. Such a diagnosis is fully justified, however, when the clinical and histological data are considered side by side and are correlated to one another, as was done in the present instance.

2. Traumatic Pulsating Exophthalmos.—William Zentmayer says there can be little doubt that in the majority of cases of traumatic origin the lesion is a rupture of the internal carotid in the cavernous sinus, and that the dilatation of the ophthalmic veins and of the nasofrontal and angular veins is the result of the venous stasis thus created. It therefore seems logical to seek to prevent the stasis rather than to remove the end-result. An analysis of the 29 cases collected in this paper shows that the common carotid was ligated 16 times, resulting in a cure in 7, improvement in 5, and failure in 4. Common ligation of the common carotid and the ophthalmic vein was done once, resulting in a cure. Combined ligation of the internal carotid and facial vein was done once, resulting in a cure. Ligation of the orbital veins was done once, resulting in slight improvement. Slow ligation of the carotid was done twice, resulting in one cure and one slight improvement. Ligation of both carotids was done once, resulting in failure. Compression of the carotid

and internal treatment was followed in four cases, resulting in cure in two cases, improvement in one, and in one the result was unknown. Gelatin injections were used in one case, resulting in a cure. There was no treatment in six cases.

3. Some Technical Features of Laminectomy for Spinal Disease and Injury.—Charles A. Elsberg. (See MEDICAL RECORD, July 1, page 34.)

4. Some Bodily Changes During Anesthesia.—Frank C. Mann presents an experimental study and states that a study of the blood of dogs subjected to etherization demonstrated the following facts: The amount of circulatory blood is diminished about 10 per cent. after from six to nine hours of light etherization. There are variations in the cholesterin values, but the changes are not uniform. The specific gravity does not change under light etherization, and under deep anesthesia increases only as asphyxia becomes a factor. The number of red corpuseles, the amount of hemoglobin, and the fragility of the red cells do not change. There is always a leucocytosis in ether anesthesia. The degree of leucocytosis varies from a very slight increase in the number of cells to more than double the normal number. The increase is usually present after from three to four hours of etherization, and is due mainly to cells of the polymorphonuclear form. The leucocytosis is not dependent on the spleen and is not prevented by atropin. It is probably the result of a direct action on the bone marrow. Phagocytic action is certainly not depressed by an etherization period of from five to six hours.

6. Stab Wounds of the Chest Involving the Diaphragm with Diaphragmatic Hernia or Evisceration.—Charles C. Green. (See MEDICAL RECORD, July 1, page 36.)

8. Heterophoria in Children.—Wendell Reber submits figures which would indicate that one in 183 of all refractive cases will represent a child with an essential heterophoria, and that one child in 10 that exhibits muscular imbalance will need some manner of treatment for its abnormal muscular status. An analysis of 35 cases is reported. He concludes that heterophoria in children is in a certain proportion of cases an entity which must have some kind of attention. Painstaking consideration of all the general physical factors is most imperative. Thorough-going correction of the refractive status is imperative, but in some cases it is merely "first aid." Exophoria when intrinsic will probably be best met with weak prisms (from 1 to 2 degrees), bases *out*, plus lateral rotation exercises. Exophoria when intrinsic will often respond to training alone, frequently will need prisms, bases *in* (from 1 to 2 degrees), for permanent use, and rarely comes to operation. Hyperphoria when intrinsic almost always demands vertical prisms of from one-third to one-half the total infinity deviation, and when paretic will more frequently than any other muscular anomaly justify operative interference.

9. Blood Transfusion, with Special Reference to Group Tests.—Walter V. Brem describes the technique and rationale of the method of blood grouping and presents the following conclusions: The practical working out of our group tests and method of transfusions has proved most satisfactory. We have determined the groups of numerous donors and have made Wassermann tests on their bloods. Our laboratory keeps in touch with these donors, who are glad to give several hundred cubic centimeters of their blood for a small amount of money. They come to the laboratory, and, by the needle and vacuum flask method, we withdraw the quantity of blood desired, having first cocainized the skin over the vein. Some of these donors have been used many times during four years. They lose no time from work, the procedure is practically painless, they feel that the money is easily earned, and the patient is under no obligation to the donor. Having our donors classified and knowing their Wassermann tests are negative, we are in a position to give transfusions quickly. A group test of the patient's blood requires only a few minutes after the blood is obtained, and then we can summon the correct donor. The method is simple and easy for everyone concerned, and the results, as far as I can judge from the literature, are as satisfactory as from other methods of transfusion. The defibrinated or citrated blood is injected intravenously through a needle without previous incision of the skin. The skin is cocainized at the time of injection.

7. Annual Report for 1914 of the Registrar General. (To be concluded.) John F. W. Tatham.

1. Injuries of the Eye and Orbit.—Arthur D. Griffith says that in analyzing 350 consecutive cases from active service he finds that 25 per cent. are cases of active injury to the eye or orbit and 15 per cent. are cases of a condition that is a rarity in peace practice, and which may be called "shock amblyopia." This term is applied to diminution or loss of vision following a shock in which no structural change is produced in the eye or optic nerve. The shock is usually from the explosion of a shell or grenade near the patient, though it may be due to other causes. In discussing wounds of the globe the author states that if one eye is ruptured it should be removed. If both eyes are ruptured, as a rule, they should be left. He would rather remove many damaged eyes unnecessarily than allow one patient to become blind through his fault. Where one eye is injured, the signs to look for in the sound eye are photophobia, lacrymation, and circumcorneal injection. These constitute the picture of sympathetic irritation. If it is decided to remove an eye there are two ways of doing this, by evisceration or by excision. The operation which the writer has performed in the majority of cases is an amputation of the anterior part of the eye, leaving the longest stump which can be covered by the flap of conjunctiva. Conjunctiva and Tenon's capsule are divided circularly, going behind the wound if possible, otherwise excising it. These membranes are turned back as a cuff for at least one cm., and the anterior part of the eye amputated at this level, or farther back if that is rendered necessary by a scleral wound. The contents of the sclera are turned out and every trace of choroid removed. An operation which has some place in war ophthalmology is exenteration of the orbit. This consists of removing the whole of the contents of the orbit except the periosteum. The object is to provide the fullest possible drainage for the orbit. The writer has done this in two instances.

4. Operative Treatment of Osteoarthritis.—W. I. deC. Wheeler describes the operations which he performed for the relief of crippling osteoarthritis of knee and the hip joint and shows *x*-ray pictures illustrating the condition of the patient three years after the operation. The first operation was performed on

the knee joint, the lipping of the tibia being carefully removed through a well-marked line of cleavage. A weight and pulley were attached to the limb for ten days and massage was administered for a short time subsequently. A few days after the operation the joint could be extended and flexed without pain. A month after the first operation the right hip joint was opened through Kocker's posterior incision. The capsule was freely opened and, while the hip was rotated freely in all directions, the newly formed bone was chiseled away from about two-thirds of the circumference. On the following day pressure on the heel caused no pain. Eight months afterward the patient walked without crutches and with perfect comfort. There are three classes of patients that receive benefit by operation. Cases in which there is a line of cleavage between the new and old bone; cases in which irregular osteophytes form in connection with the joint in such a way as to produce ossification in the fibrous layer of the capsule, and cases of rheumatoid arthritis in which there is destruction of the joints without osteophytic outgrowths. This form of the disease is common in young people and much can be done for them by the administration of vaccines if the focus can be found. If the cases are cryptogenic attention should be directed to the condition of the large intestine.

5. On the Agglutination Reaction of the Bacilli of the Typhoid-Dysentery Group with Normal Sera.—T. R. Richie states that since the appreciation of the actual facts regarding "normal" agglutination of the organisms in the group under discussion is a very pressing matter in view of the many enteritis cases to be investigated at the present time, in association with Dr. Rajoman and Dr. Western, he undertook the examination of a series of normal, so as to determine the normal mean agglutination for the bacilli in question when examined with the technic in use in their laboratory (Bacteriological Laboratory of the London Hospital). The blood of 792 persons was tested, and none of them, so far as they were aware, had suffered from any infection by any organism against which the sera were being tested. The writer describes the technique which he and his associates used and gives the following general summary of his conclusions: 1. *B. Typhosus.*—(*a*) Complete agglutination in a dilution of 1-16 should be looked upon with considerable suspicion. (*b*) Complete agglutination in a higher dilution (1-32 or above) should be looked upon as diagnostic. *B. Paratyphosus A and B.*—Complete agglutination in a dilution 1-16 is suspicious, and in 1-32 or higher may be looked upon as diagnostic. *B. Dysenteriæ* (Shiga).—Complete agglutination in a dilution of 1-64 and above should be regarded as diagnostic. *B. Dysenteriæ* (Flexner).—Complete agglutination in a higher dilution than 1-128 should be looked upon as diagnostic, but in a dilution of 1-128 or lower it cannot be relied upon for diagnostic purposes. 2. In the case of medical students, laboratory workers, and the hospital class of the population, the tables given show that a larger percentage respond to the test in higher dilutions than do "normal" members of the population. This must be taken into consideration in applying the above conclusions.

2. The Theory of Blood Pressure Measurement.—Leonard Hill and James M. McQueen call attention to the difficulties and disagreements met with in the study of blood pressure measurements and state that in order to give accurate information on the factors concerned in blood pressure measurements a scheme must permit of compression being applied to an artery in a pulsable and not rigid manner, and a rise of a peripheral resistance *pari passu* with increasing compression must be arranged for. When an armlet or bag of Hill's pocket sphygmomometer is made to compress an artery where it lies on bone or with little tissue around it—for example, temporal, dorsalis pedis, aberrant radial—it deforms the artery and prevents the passage of the pulse at a pressure less than diastolic. The finger of the physician acts in the same way, and therefore cannot estimate the systolic pressure accurately. Compression of the tissues surrounding the artery so as to block the venous outlets is essential to accurate blood pressure measurement. This congests the blood beneath and beyond the armlet or bag. The pulsing of the congested mass of tissues renders armlet or bag capable of delivering a circular compression to the artery, and one which yields to the pulse and prevents deformation of the artery until the systolic pressure is overtopped. Sufficient area of veins must be blocked if the blood pressure measurement is to be an accurate one, consequently the bag or armlet must be broad. The bag, together with the observer's hand, inclose the forearm, and so makes the bag of Hill's instrument equivalent to the armlet. Failure to make the bag broad enough accounts for many of the inconsistencies in the literature of blood pressure measurement.

3. The Systolic Pressure in Acute Nephritis.—Rodolf G. Abercrombie has recently treated at a base hospital in France several hundred cases of nephritis occurring among the soldiers, and has taken advantage of the opportunity thus afforded for the study of the blood pressure during the acute phases of this disease. He has found that the blood pressure is always raised during some stage of the course of the disease, although not to so great a height as in the case of chronic nephritis. Wide diurnal variations in the pressure were usually present, the pressure being highest in the evening. Associated with this evening rise of temperature there has been paroxysmal dyspnea and headache. Usually the amount of albumin diminished *pari passu* with the fall in pressure, although residual albumin often persisted after the pressure had fallen to normal. Sometimes, however, the two curves bore no relation to each other.

6. Causation and Cure of Certain Forms of Lunacy.—Rupert Farrant publishes a summary of his study of the causation and cure of certain forms of lunacy carried on during the last seven years. He states that it is a continuation of that previously published on the thyroid gland in the elucidation of goiter and exophthalmic goiter. This work consists of the microscopic examination of sections taken from the pineal, pituitary, thyroid, and sexual glands—first at different ages and periods of life; secondly, the effect induced in these glands by the acute and chronic toxemias, and, thirdly, the changes found in cases of lunacy. From the examination of some 3,000 specimens it is found that these glands differ at different ages and periods of life; with advance of life they tend to atrophy. It is found that the pineal and pituitary react to certain toxemias, the ultimate result of which is fibrosis. The re-

lation of the thyroid to certain toxemias with the induction of hypertrophy, cysts, and adenomata the writer has already described in a former article. In primary and secondary amentia, atrophy of the pineal, pituitary, and thyroid were found in three main groups of cases. In dementia præcox and other cases of dementia an alteration was found in the glands which varied with the duration of the case. In some cases of acute confusional mania, melancholia, manic-depressive, and other forms of insanity, changes were found in the thyroid, pituitary, and the sexual glands. The changes varied from hypertrophy to atrophy. The pituitary gland was found sometimes to have given rise to symptoms of hyperpituitarism and ranging to apituitarism, in idiocy, dementia præcox, and other forms of insanity. The thyroid gland was frequently found to be abnormal in children, adolescent, and adult lunatics. Signs of alteration in the pineal were found especially in children and adolescents. Alteration was found in the sizes of the testicles associated with ductless gland changes. Pyohhea and carious teeth were found to be a frequent accompaniment of lunacy in adults. The writer has deduced that many cases of lunacy may be classified according to the toxemia present and the change that it has induced in the ductless glands. Alteration in the sexual glands, whether primary or secondary, leads to altered mentality up to insanity. The lines on which treatment may be carried out based on this view of the pathology is that toxemias, if present, should be removed by medicinal or surgical measures and the glands allowed to involute if they are hypertrophied, or if they are degenerated with deficient secretions these secretions should be supplied. Good results may be expected before cortical brain lesions have taken place.

Berliner klinische Wochenschrift.

March 20, 1916.

Isolated Sclerosis of the Pulmonary Artery.—Hart states that isolated genuine sclerosis of this vessel in the young is undoubtedly rare. Not many cases are on record. Romberg was the first to show that the lesion may be isolated and unaccompanied by symptoms. In 1912 Schneller and Schumacher attempted to collect the recorded cases, but included numerous cases which were not strictly isolated. The author recognizes but five cases, with possibly a sixth, in which there was a slight sclerosis of the aorta. These agreed not only pathologically, but clinically—cardiac disturbances ending in insufficiency, edema, and cyanosis, increased cardiac dullness to right, murmurs over all valves, with predominance of mitral, and small and rapid but regular pulse. The diagnosis was congenital heart lesion, presenting especially mitral insufficiency. Autopsy showed a high degree of hypertrophy of the right ventricle, but with fully intact valves and marked sclerosis of the pulmonary artery. To these five (six?) cases the author has the rare good fortune to add two more. 1. A woman of 30 came to autopsy with the diagnosis of myodegeneratis cordis. She was highly dyspneic and cyanotic and murmurs were heard over the entire greatly enlarged heart. No history was available. The second case was in a young woman of 25. The cardiac troubles had begun a half year before and had rapidly increased until three weeks before she had become bedridden with cyanosis, dyspnea, and marked palpitation. The symptoms were typical, as given above, but the diagnosis at the time was stenosis and insufficience of the mitral. Death soon supervened. In both cases the autopsy finds were startling, especially in the second case, in which a positive diagnosis had been made. The right heart in both cases was hypertrophic while the left was atrophic and appeared like a rudimentary appendage. Elaborate studies in some of the recorded cases showed that the sclerosis of the pulmonary artery, albeit isolated, differed in nowise from the same lesion when part of a generalized arteriosclerotic process. As for the etiology one patient had been a heavy beer drinker who had suffered originally from beer-drinker's heart, a condition which would throw strain upon the pulmonary artery of a purely mechanical character. Had some toxic factor been present other vessels would probably have suffered. An entirely different causal nexus must have been present in the author's case, in which the left heart had become atrophic, as is sometimes the case in mitral disease. Apparently the left heart withers because of a blood scarcity. The relation of pulmonary sclerosis to hypertrophy of the right heart is not clear. Which is primary and which secondary? The author holds that the vascular lesion occurs first.

Cystoscopy and Radiation in Inoperable Cancer of the Uterus.—Heimann states that cystoscopic control in the radiation treatment of uterine cancer has become an accepted procedure. The latter is best shown in certain cases. Thus in a woman of 49 the portio has been transformed to a cauliflower the size of a hen's egg, which bleeds freely on contact. Both parametria are infiltrated, worse on the right. The cystoscope shows a small bladder, markedly bulging over at the trigon. Marked transverse folds, tumefied. Mucosa injected. Ureteral openings cannot be brought into view. After the combined use of mesothorium and deep radiation, the cancer vanished, the vaginal walls came together, the bladder had improved so that both ureteral orifices could be brought into view. In a second case a similar condition of the bladder became almost normal after the disappearance of the cancer. The improvement in the situation, size, and condition of the bladder does not always run parallel with the improvement in the cancerous growth. When the condition of the bladder is one of parietal edema the viscus may return to its normal condition save when the growth of the cancer has caused deep-seated changes in the vascular apparatus. When these are severe we find the so-called bullous edema, as the lymph, no longer able to escape, causes a detachment of the epithelial layer. Beyond this comes actual perforation. All kinds of results are seen in the course of radiation. The edema may disappear, remain unchanged, or grow worse. Bullous edema has been seen to disappear after radiation. As is known, the state of the bladder is a factor in determining operability. In regard to the infiltrated parametria these become softer after treatment in favorable cases. In one of the author's cases an initial success was not maintained and matters rapidly changed for the worse. But whether treatment is of benefit or not cystoscopic control is equally serviceable.

Old Substitutes for Scarce New Remedies.—Servoss thinks that the scarcity of syntheties is not an unmixed evil. Some old forgotten resources may now be profitably revived, such as colchicum for rheumatic affections, which with alkalis can in part replace the salicylic derivatives. Aconite and veratrum have been neglected for coal tar antipyretics, and the same is true of henbane and lobelia as antispasmodics. We no longer use conium or gelsemium, although they can often replace morphine, while hyoscine properly given is a better hypnotic than sulphonal or veronal. The author sees no harm in borrowing from the selective materia medica under the circumstances. We should make a trial of it, at least, and if any remedies are dependable credit should be given where it is due. He makes this suggestion fully realizing that it will not be popular with the profession, who, however, are slavish in their attitude toward foreign manufacturers. —*Indianapolis Medical Journal.*

Society Reports.

AMERICAN NEUROLOGICAL ASSOCIATION.

Forty-second Annual Meeting, Held at Washington, D. C., May 8-10, 1916.

THE PRESIDENT, DR. LEWELLYS F. BARKER OF BALTIMORE, IN THE CHAIR.

Monday, May 8—First Day.

War and the Nervous System. — Dr. LLEWELLYS F. BARKER of Baltimore delivered this address, saying that as the result of the studies which had been made during the present European war our knowledge had been enlarged in reference to organic nervous lesions, functional nervous disorders, psychiatry, and normal psychology. So far as wounds of the brain and spinal cord were concerned, the accepted views regarding topical diagnosis were being corroborated. It had been established that certain organic lesions of the central nervous system might be caused by modern high explosives without external wound. Surgeons were unanimous in urging the thorough investigation of every head wound, no matter how trivial it might at first seem to be. As regarded the peripheral nerve injuries, it had been shown that loss of power due to section of tendons or muscles might sometimes be confused with paralysis due to lesions of the nerves themselves. Contrary to what many had expected, nervous states not due to organic lesions, though fairly numerous, had in reality made up but a very small proportion of the total number incapacitated by the war. All the well-known types of the functional nervous disturbances had been met with. While the number of simulators and malingerers was large, those more experienced in the psychoneuroses believed that the number of true, or vulgar, simulators was very small. It had been pointed out that malingering was itself a psychological symptom. As regards the psychoses, it was surprising that such a small number of cases of insanity had been reported. It was asserted that the majority of soldiers in whom psychoses had been observed either had had symptoms of the diseases before the war or had given definite evidence of predisposition to mental disorder. The evidence seemed to favor the view that the human nervous system was to-day better able to stand strain than ever before in its history.

The Differentiation and Organization of Sensations. —Dr. STEWART PATON of Princeton, N. J., read this paper, in which he said there were two points he wished to emphasize as the result of observations upon the embryos of some of the higher vertebrates: First, the great necessity of looking at the neurological phenomena from a broad biological standpoint. Second, he wished to emphasize, if possible, the great value that came to us from a study of comparative neurology. In the chick embryo of 55-57 hours of incubation he had found the motor half of the reflex arc developed far in advance of the sensory half. This tract was developed from the lower caudate quarter of the cord up to the level of the third nerve. At 120 hours one could follow the development of the third nerve to its terminal distribution. Evidently this was an ancestral inheritance. The sensory half of the arc was very gradually superimposed upon the motor sector. When the embryo first responded to stimuli from the outside world we found that the first organ to come in and modify our responses was the thyroid; a little later the adrenals. At this period, 120-125 hours, there was a perfectly enormous differentiation in the sympathetic nervous system. Only very much later did the sex organs apparently come into the neural circuit.

Neuraxial Differentiation of the Fibers from the Horizontal and the Fibers from the Vertical Semicircular Canals, Demonstrated by Means of the Bárány Tests.—Drs. CHARLES K. MILLS and ISAAC H. JONES of Philadelphia prepared this paper, which was read by Dr. Jones, who said that no matter where the primary seat of the affection which caused vertigo might be situated, whether in the stomach, kidney, liver, pancreas, tonsils, or the brain outside of the vestibular apparatus, the resulting toxemia, the abnormal nervous stimulus, or the cardiovascular did not produce vertigo until the vestibular apparatus—the labyrinth and its associated pathways and encephalic centers—was involved. The Bárány tests furnished them with the means for studying this vestibular apparatus. These tests enabled them to say with more positiveness that an intracranial tumor, abscess, or other lesion was situated in the third ventricle, the cerebellopontile angle, was limited to the pons or the cerebellum, or was labyrintnine. Cajal had shown histologically that fibers from the vestibular portion of the eighth nerve entered Deiter's nucleus and continued from the inferior cerebellar peduncle into the cerebellum itself. This tract had been generally recognized and accepted. The writers believed (1) that this path included the fibers from the horizontal semicircular canals exclusively, and (2) the fibers from the vertical canals had an entirely different course. The former were confined to the oblongata, while the latter ascended into the pons. In thirty-two cases in which the labyrinths themselves and the eighth nerves were normal and the horizontal canals gave normal reactions, the vertical canals failed in some or all of the well-known responses. That the labyrinths themselves were normal was made probable by the presence of perfect hearing, and corroborative evidence of neuraxial lesions was additional confirmation. In five cases stimulation of the vertical canals produced no nystagmus, no vertigo, and no falling, and yet violent projectile vomiting occurred. This showed that the vertical canals themselves were functionating; in fact, there was even a hyperactive response of the tenth nucleus to the stimulation of the canals. In one case in which the lesion was clearly thrombosis of the right posterior, inferior cerebellar artery the right horizontal canal failed to respond normally, whereas reactions from the right vertical canals were normal. They believed that the ear stimulus which produced vertigo passed to the cerebrum through the cerebellum. While the paths which carried vestibular stimuli through the cerebellar to the cerebrum were not demonstrated absolutely in all their extent, the facts at their disposal appeared to indicate that they were received by the cerebellum through the inferior cerebellar peduncle from the horizontal canals and the middle cerebellar peduncle from the vertical canals, and after completing their cerebellar itinerary pass to the cerebrum by way of the superior cerebellar peduncles. In the experience of the writers interruption of the impulses from the vertical canals was produced by tumors of the cerebellopontile, internal hydrocephalus causing pressure on the floor of the fourth ventricle, and intracerebellar tumors causing pressure on the pons. Finally, they were confident that the fibers from the horizontal canal and the fibers from the vertical canals had separate pathways in the neuraxis. That the horizontal canal fibers were confined to the oblongata and entered the cerebellum through the inferior peduncle and that the vertical canal fibers ascended into the pons and entered the cerebellum through the middle peduncle, however, they believed to be highly probable, but felt that their evidence to date was not sufficiently large to indicate with confidence the exact course of these fibers.

Sensory Disturbances of Cerebral Origin. — Dr. ALFRED GORDON of Philadelphia read this paper, in which he presented the records of nine anatomoclinical cases distributed as follows: Four cases of cortical lesions, three of capsular, one of thalamic, and one of pontine lesion, and called attention to the special characteristics of each of these groups and the differential features in regard to the sensory disorder. He found that the generally adopted views concerning sensory disturbances of cerebral origin did not always present the real condition. For example, in one of his cases there had been a large hemorrhage strictly limited to the parietal lobe, nevertheless there had been a hemiplegic condition on the opposite side. Also in a case with involvement of the very posterior portion of the internal capsule which was supposed to be purely sensory in function there had been no sensory disturbances at all during life. His conclusions from this study were that, in spite of the generally accepted views concerning sensations of cerebral origin, certain conservative reservatons should be made whenever diagnostic deductions were to be made.

Dr. DAVID I. WOLFSTEIN of Cincinnati said that a colored man had come into the receiving ward but had not been admitted because nothing could be recognized He had come a week later, and it had been found that he had localized convulsions of the face and arm and there was very complete arteriosclerosis. He also had a loss of the position sense and impairment of the localizing sense. The *x*-rays showed that he had been stabbed in the head with a penknife and that a piece of the blade was extending into the precentral convolution. The blade was extracted and the man recovered promptly from the convulsions, but the arteriosclerosis and the disturbance of the sensations remained as before.

Dr. Herman H. Hoppe of Cincinnati said that he recalled a case of tumor in the arm center in which the first manifestation had been pain in the tip of the finger, this disturbance of sensation preceding the Jacksonian seizures. The tumor had been located in such a way as to cover both the ascending and the parietal lobe. It was impossible to tell where it originated.

Some Unusual Features of Jacksonian Convulsion.—Drs. Samuel Leopold and E. Murray Auer of Philadelphia, in a paper prepared by them and read by Dr. Leopold, reported a number of cases showing unusual features of Jacksonian epilepsy. Diphtheria had been the etiological factor in one case. Unilateral sensory phenomena associated with hydrocephalus had been noted in one of the cases. The presence of thalamic pains, together with Jacksonian convulsions, verified by necropsy, constituted one of the unusual manifestations. Jacksonian convulsion had occurred in cases with the lesion located at a distance from the motor cortex. The peculiar manifestations of Jacksonian attacks in syphilis were noted in two cases.

Spasmodic Tic Produced by Cerebellopontine Tumors.—Dr. Harvey Cushing of Boston read this paper, stating that a patient had been sent to the Brigham Hospital with the diagnosis of right parietal tumor producing Jacksonian attacks of the left face. His assistant arrived at the same conclusion on seeing the patient. It seemed typical. The patient was conscious and could turn his head, even though the attack was going on. He was very certain on two or three occasions that the attack and spasm, with the sensory disturbance which he said came with it, had spread into the arm and side. In going over him carefully it became evident that this was a cerebellopontine tumor of the usual type, and upon operation a tumor had been found relatively early and removed in so far as one was justified in removing these things, leaving the capsule. In a series of fifty to sixty pontine cases this had been the only case in which he observed these definite attacks, and this began originally as nothing but a little blepharospasm of the left eye. He had been having attacks every ten minutes when he came in. They subsided after operation. Here was a peripheral lesion which caused weakness in the face, but less commonly produced spasmodic tic, which might be mistaken for Jacksonian attacks. Since that he had seen one other example of almost exactly the same kind.

Dr. J. Ramsay Hunt of New York said that he had in his papers upon the sensory route of the facial nerve emphasized the production of reflex spasms of the face. He had had a series of cases of reflex quiverings and spasms of severe degree. In one case there had been spasm of the auricular mechanism only. Evidently only certain cells of the facial nucleus had been in a state of excitability. Therefore he did not think these cases necessarily depended upon pressure upon the pons.

Dr. W. G. Spiller of Philadelphia said that some years ago Dr. Mills had had a case of spasm confined to one side of the face which at necropsy showed tumor of the cerebellopontine angle. Dr. Spiller had had a case of a man struck on the right side of the forehead. He said that the eyelids of both sides were affected. Dr. Jones concluded that there was a tumor of the cerebellopontine angle, and this was confirmed by necropsy.

Dr. W. B. Cadwalader of Philadelphia remarked that in a case which he had observed there were clonic movements of one side of the face without loss of consciousness. It was decided that there was probably a cerebellopontine growth, and autopsy showed an endothelioma a short distance anterior to the eighth nerve.

Stock-Brainedness. The Causative Factor in the So-Called Crossed Aphasias.—Dr. Foster Kennedy of New York presented this paper, in which he said that the cause of the indecision in regard to the location of the speech centers, and, therefore, the causation of the aphasia, lay in the fact that apparently irrefragable evidence could be produced by the protagonists of each of the different views. The cases used to disprove the validity of Broca's area only impugned the theory of constant conjunction of right-brainedness and left-handedness, or vice versa. The conviction had grown, therefore, that there was truth in both dogmata, but that adequate explanation of many anomalous cases could not be given without the injection into the argument of some new factor not as yet brought under scrutiny. The author desired in the most tentative fashion to suggest that the simple statement that a given patient was right- or left-handed was not adequate in the light of some cases to be mentioned later. No more information than was contained in this somewhat bald announcement had been given by any of the writers on this topic saving Byrom Bramwell, yet it would appear that not only by investigating the question of a patient's handedness but also the prevalent type of handedness in his stock would throw light on a very obscure chapter of neurological medicine. In the literature of aphasia one found that but few cases disagreed with the general hypothesis that in right-handed persons the centers of language were situated on the left side of the brain. In the few instances where aphasia had resulted from injury to the right brain, some anomalous and adventitious circumstance had usually been brought forward to account for the situation. It would appear, then, that from the cases reported in this paper this trend, when present in the stock, might produce in the few right-handed individuals of the sinistral stock a condition of brain similar to their collateral relatives and ancestors, with the result that the speech area in such persons came developed in an ectopic position.

Dr. Hugh T. Patrick of Chicago said that about thirty-three years ago, when he was a medical student, Dr. Janeway gave a sort of rule of thumb in deciding on who was right-handed and left-handed, a rule which seemed to work pretty well; that is, that a left-handed person must be a left-handed writing person. All other activities were of less importance.

Dr. Joseph Collins of New York City said that it was currently reported or spoken of in literature that the majority of children were left-handed. That was widely believed. However, credible statistics showed that only about 5 per cent. of adults were left-handed. There must be a serious mistake on one side or the other. He was inclined to think that it was on the side of those who believed that children were all left-handed or that the majority of them were left-handed. Second, to all rules there were exceptions. It was quite possible that some of these cases referred to by Dr. Kennedy were exceptions to the rule, which was that the speech area of left-handed individuals was on the right side of the brain. Third, if Dr. Patrick would substitute fighting for writing he would agree with him. If a man fought with his left hand he was left-handed. If a man did the primitive things of life, the things that were necessary in order for him to continue his activities, he was a left-handed individual. Dr. Collins said that he was left-handed, but did all such things as writing, golf, and drawing with his right hand; in striking, at least in doing any of the fundamental things, he was left-handed. He was inclined to believe that the executive speech area might be vicariously assumed by areas of the brain adjacent to the injured part of the brain, which would explain the majority of cases which were exceptional to the generally established rule.

Dr. E. B. Angell of Rochester, N. Y., said that some years ago a woman of thirty-two had come to autopsy for brain tumor. As a child of five she had thrombosis of two-thirds of the operculum and part of the motor tract of the left side. As a child she had been right-handed. As the result of the hemiplegia and loss of the power of the right arm she had to develop the left hand. She regained the power of speech. At the autopsy were found the remains of the destructive process of the old thrombosis. The right side corresponding to the right operculum and the right motor hemisphere were much enlarged. The cortex was much thickened, showing the influence of the change from right to left as she grew up to womanhood.

Dr. Charles K. Mills of Philadelphia said that he felt more like responding to the discussion by Dr. Collins than to the paper by Dr. Kennedy, although both, of course, went together. There was nothing he disliked so much as to disagree with Dr. Collins, as everybody knew, but he thought Dr. Collins was altogether wrong about this thing of the primitive instinct of preservation. This did not have to do with the faculty of speech and development of one or the other hemisphere. It was the educational acquirements of the brain that had to do with this. It was very true that Dr. Collins might be able to hit out with his left hand, but he would say that the probabilities were that he hit out with both sides of his brain, with speech as well as in other ways. He believed Dr. Kennedy had really the right explanation. If you had the inheritance of speech through many generations with the inheritance of right-handedness, the left-handedness in a given generation was then sort of an accidental deviation, so to speak, and it didn't have the force that it would have had if the left-handedness had been inherited through many generations.

Dr. J. Ramsay Hunt of New York City said that, in the interest of harmony between Dr. Mills and Dr. Collins, he would suggest that Dr. Collins was both right and wrong; that some of his functions he performed with the cortex and some with the globus pallidus. Many of the acts, for instance fighting, must be referable to the automatic mechanism. So we saw that a man could be right-sided in regard to the globus pallidus.

Dr. Bernard Sachs of New York City said that it was a fact that the majority of children were, in the ordinary sense, born ambidextrous, and the important thing was that most people became later in life absolutely right-handed. Another point was that the loss of speech defect was associated with loss in both hemispheres about equally, and it was only later in life that the preponderance of the left hemisphere had become well established. He believed there were different groups of cases. The ordinary child born ambidextrous could be made a right-handed child. There were some individuals who never could be made right-handed. He positively believed that the larger number of people were right-handed because they were made so by education.

Dr. W. G. Spiller of Philadelphia said that he had had occasion to examine a child bearing out Dr. Sach's statement. A child born right-handed had been burned in a gas flame and had been unable to use the right hand for five or six weeks. During that time he used the left hand, and when the bandage was removed continued to use the left hand. It required training to induce the child to resume the use of the right hand. Undoubtedly, if the effort had not been made to train the right hand the child would have continued using the left hand.

Dr. Francis X. Dercum of Philadelphia remarked that if his recollection served him correctly, the right side of the child was larger at birth. He thought there was more muscle tissue in the right side than in the left. It could not be merely a matter of training, but if the right hand was injured the left hand was trained.

Dr. Harvey Cushing of Boston said that he thought it might be of interest to call attention to a fact that was well known that right- and left-handedness went back into other forms of life than mammals. It was a matter that was of interest even to Leonardo da Vinci, who made a study of spirals. Occasionally there was a left-handed reversal of this form. In certain shells, perhaps one out of ten thousand, there was a left-handed spiral, all the remainder being right-handed. Then, too, he believed that parrots were right-handed, or right-clawed, as a rule, and whether or not any experiments had been made to ascertain whether this could be altered by removal of speech he did not know.

Dr. Alfred Reginald Allen of Philadelphia stated that the blood supply of the human being and most mammals and vertebrates was not symmetrical with the vertical axis. It was probable that the left side of the brain might get a better blood supply than the other side of the brain.

Dr. Isaac Adler of New York said that he had been making some cranial measurements and ran across a peculiar relation of the right hemisphere. In the right-handed person the right parietal lobe was more prominent than the left. In the left-handed person it was not so. It was about equal. The conclusion was that most left-handed people, therefore, were ambidextrous.

The Effects of Laminectomy and Simple Exposure of the Cord Upon the Reflexes and Upon Some Symptoms of Spinal Disease.—Dr. Pearce Bailey and Dr. Charles A. Elsberg of New York City prepared this paper, which was read by Dr. Elsberg, who stated that in a large number of spinal operations remarkable changes in the skin and tendon reflexes had been observed. Laminectomy and exposure of the spinal cord frequently had a marked influence upon the symptoms and physical signs of spinal disease. In some instances complete and permanent relief had followed the operation.

Dr. E. Sachs of St. Louis said that there were two points which struck him forcibly; that was, that these changes lasted only at most forty-eight hours, frequently only twenty-four hours, and in the second place, that, with one or two exceptions, most of the changes he recorded were changes in which spasticity improved to the point of normal reflexes or in which normal reflexes subsided and became really subnormal. He would like to ask Dr. Elsberg whether a possible explanation might be that it was due to a temporary loss of cerebrospinal fluid. He thought that it had been demonstrated pretty conclusively that it took from welve to forty-eight hours for cerebrospinal fluid, if it had been lost in a considerable quantity, to reform. In the second place, these symptoms that he had described might be due to a cutting of the inhibitory influence of the central nervous system. Might it not be that the temporary removal of the cerebrospinal fluid opened these central paths again and in consequence the inhibition of the central nervous system came into play again?

Dr. James J. Putnam of Boston said that he should like to call attention in the first place to the fact that Fritzig many years ago reported certain effects due to laying bare the cortex of the brain. Simple exposure had a very considerable effect. A great many years ago Dr. Putnam had had under his care a patient with an intramedullary spinal tumor which had been operated upon by Dr. Keen of Philadelphia, with the result of finding that nothing could be removed. Then the patient went on with complete paralysis of his leg and then he developed very intense, almost unbearable pain in the arms. Dr. Warren then operated again. He could not say exactly whether the operation had been done in the cervical region, but he thought not. He thought that the idea was that a free exit should be obtained for the cerebrospinal fluid and the other operation had been done in the dorsal region. At any rate, the spinal canal had been reopened and, to their great pleasure and surprise, the patient's pain went away and never came back again as long as he lived. He had done, as Dr. Putnam dared say others had, quite a good many lumbar punctures for the relief of dizziness. In trying to explain the favorable result in these cases he could not find any better way to account for it than that it broke up the habit of the nervous system. He thought there was distinctly such a thing, and knew there was as regards functional nervous disorders, and he thought there might be as regards the organic processes of what we might call state or habit; and it happened now and then that, when some considerable influence came into temporary play changing this, the set character of the process that was going on might be altered. At any rate, in a great many kinds of conditions one saw results that could not be explained under any other hypothesis.

Dr. Foster Kennedy of New York said that he would ask if Dr. Elsberg did not consider that in an operation done on the spinal region or any operation a great many factors entered into the procedure. One of them was essentially the anesthetic. He thought he had seen in cranial cases, as well as in spinal cases, when the patient was coming out of the anesthetic, that the reflexes were abolished, and he had seen an extensor plantar reflex and so-called Babinski sign not change to flexor but become absent and later reappear as before. He would suggest to Dr. Elsberg the question as to whether or not the anesthetic had any influence.

Dr. Francis X. Dercum of Philadelphia said that this discussion recalled to his mind some experiences he had had with the late J. William White at the Philadelphia Hospital quite a number of years ago, in which they noted a quite persistent improvement in several of their cases for which they could not account. They had found no lesion in the cord and the patients simply got better after the laminectomy. Dr. White and himself wrote a paper upon the subject, entitled "The Value of Operation Per Se." They thought it due to some unexplained improvement of nutrition, something that brought more blood in the healing process to the wounded cells, and that the nutrition of the cord itself was raised and some restoration of function followed.

Dr. E. W. Taylor of Boston said that some work that he had been doing for a couple of years might perhaps throw some side light on this question. In cases which had been anesthetized, no matter what the operative procedure, invariably the acetone and diacetic acid varied anywhere from 36 to 72 hours, and the muscular and mental activity of these patients was pretty near parallel with the persistence and amount of acidosis, and he would feel that the change noted in these cases was one of depression and that perhaps an investigation along the line of acidosis in the changes in the reflexes would be fruitful.

Dr. Joseph Collins of New York said that he thought that the explanation that Dr. Taylor had just given was the proper explanation and the one that would stand the test. He would suggest, therefore, and would put this in practice in his own cases hereafter, that the bicarbonate of soda be given in moderate saturation, as he understood that that was the surgical procedure in order to diminish the acidosis. He thought

he ought to say that in a considerable number of cases of laminectomy done by Dr. Elsberg for him there had been no improvement whatsoever in any of the morbid manifestations of disease.

Dr. Charles A. Elsberg of New York City said that they had also a theory to explain these symptoms, but did not think it was worth very much more than the other theories proposed. It was purely theorizing. They had investigated these cases from various viewpoints. They had, for example, watched the condition of the reflexes in a considerable number of patients who had been under prolonged anesthesia not only after operations on the cerebrospinal system, but other operations, and had seen suppression of the reflexes for a few hours until the patient was fully awake, but never after that. They thought very much over the question of whether the escape of cerebrospinal fluid had anything to do with it. One must remember that in opening the dura he is exposing the cord to a higher pressure than it had before. In addition to that he had injected considerable amounts of saline solution just before the cord was closed in order to have it full of cerebrospinal fluid, and it showed nothing different from those in whom the spinal fluid had escaped. The question of acetone was one that he was unable to speak about. He had examined a number of patients who had acetonemia and that had regularly a depression of normal reflexes.

Progressive Atrophy of the Globus Pallidus. A Special Form of the "Paralysis Agitans Syndrome" Occurring in Early Life and Associated with Atrophy of the Cells of the Globus Pallidus.—Dr. J. Ramsay Hunt of New York City read this paper, stating that paralysis agitans undoubtedly included a variety of types which were related clinically but which must present differences in the localization and character of the underlying pathological lesion. In the present study an effort was made to isolate a special group of paralysis agitans cases, namely, the juvenile type, on the basis of certain definite changes in the motor cells of the corpus striatum. In one case which was studied the sole lesion was atrophy and disappearance of the large motor cells of the globus pallidus system. The globus pallidus system was the motor center proper, while the neostriatum (caudate and putamen) formed an inhibitory and coordinating cortical mechanism. The mechanism which was involved in this disease was the motor or afferent system of the globus pallidus. A destructive lesion in the case of the globus pallidus produced not only paralysis of certain automatic and associated movements, a slowness of movement and loss of motor initiative but a great increase in muscular tonus as well. An affection of the small-cell system of the neostriatum released the motor mechanism of the globus pallidus from control, and there resulted the phenomena of the chorea of Huntington. A destructive lesion of both types of cells produced chorea, athetosis, spasms, rigidity, and tremor in various combinations.

Dr. B. Sachs of New York said that he was absolutely in sympathy with Dr. Hunt's efforts to separate some of the groups of paralysis agitans. One of Dr. Hunt's cases he had had an opportunity to study. The case of this boy had impressed him at the time by the fact, and he had made the statement, accordingly, that here was a case of paralysis agitans appearing in early life and with some of the symptoms that we ordinarily associated with disseminated sclerosis. In other words, when the disease occurred in early life, it had some of the symptoms which we knew always occurred in early life, although the other disease appeared later in life. He had no right, nor had he the desire, to deny that it might be due to changes in the globus pallidus and that there might be some explanation for the lesions in other cases of paralysis agitans. These changes in the globus pallidus were the only changes that Dr. Hunt was able to put his finger on. There was danger of making that the seat of the chief pathological lesion. The question arose whether they were not simple terminal changes? Had they any actual causative relation to the disease which had lasted twenty years? In a case of this sort it wou'd be absolutely necessary to see the anterior pole of the brain and the very lowest part of the spinal cord in order to be sure that we had really got at the chief changes underlying the disease.

Dr. J. Ramsay Hunt of New York said that, of course, this was only one case; but one case, if thoroughly studied, was as good as a thousand, and he felt that he was right. As to the diminution of cells, he had been very careful in making comparison with the normal count, not just guessing. Then the cells showed all the changes of chronic atrophy. Now, of course, if he had suddenly presented such a case and asked his hearers to believe that it was because of paralysis agitans, they might wonder. Wilson had come very near it with Wilson's disease. Here was a disease involving the caudate nucleus that immediately threw a light on that reflex. There were two great cell groups here, the large cell group of the globus pallidus and a smaller group. Then the phylogeny and anatomy all favored such an idea. These tracts of the system developed very early in the life of the fetus.

Werdnig-Hoffman, Early, Infantile Progressive Spinal Muscular Atrophy.—Dr. M. A. Bliss of St. Louis read this paper, stating that an apparently healthy and intelligent child, who had made the normal progress of an infant for the first few weeks or months of life, began without sudden onset, and without obvious cause, to lose power. The weakness was first noticed in the legs and in the hips; as the disease progressed the lower portion of the back became so affected that the child was no longer able to sit up. The disease pursued a progressive course, the shoulders, thighs, upper arms, forearms and legs being successively involved, and finally the muscles of the hands and feet. Fibrillar twitching of the muscles might be present in some cases. The limbs were usually absolutely flaccid, and the deep reflexes were abolished. There was no pain or tenderness, and no disturbance or sensation. The disease ran a slowly progressive course, death taking place from failure of respiration or bronchopneumonia. Although pathologically these cases closely resembled the progressive muscular atrophy of adults, they presented considerable differences. The disease started in the proximal muscles, and only later affected the hands. The atrophy was not so striking as in adult cases; in fact, the infant often appeared well nourished. Cases with spastic condition of the legs were rare. He reported in detail the cases of three children by the same mother, all apparently normal and healthy at birth, but who fell victims to this disease at the age of about nine months and died as the result of it before they reached the age of three years.

Amyotrophic Lateral Sclerosis.—Dr. John H. W. Rhein of Philadelphia read this paper, in which he stated that the subject of his report was aged 56. The symptoms were atrophy of both arm muscles, including the small muscles of the hand, the flexors and the extensors of the forearm, biceps, triceps, shoulder girdle, pectorals, and serratus magnus. There were fibrillary tremors of both arms. Both sides of the tongue were atrophied, the knee and arm jerks were exaggerated, but there was no Babinski sign or spasticity. The Wassermann reaction was positive. Death occurred about a year after the onset. The pathological study was made of the cord, medulla, pons, internal capsule, basal ganglia, corpus callosum, and cortex with Marchi as well as other methods. The results of this study were presented.

Dr. F. R. Fry of St. Louis said that some years ago he had reported a classical case of Friedreich's ataxia in a girl of twelve or fifteen years of age. At a later period the mother of this girl, who was then about forty-two years of age, developed amyotrophic lateral sclerosis. He simply mentioned that little coincidence as possibly interesting from an etiological standpoint as to whether this syndrome did not represent the same kind of amyotrophic tendency that Friedreich's disease itself was clinically considered to be.

Dr. Samuel Leopold of Philadelphia said that he had reported on this same subject. In his case the individual had died within two years. He found some round-cell infiltration, and, on looking up the subject to see what relation syphilis had with this condition. found that in about one-third of the cases syphilis played a very important rôle. So that might be a dominant feature in these very rapid cases.

Tuesday, May 9—Second Day.

Familial Spastic Paralysis.—Dr. C. Eugene Riggs of St. Paul, Minn., read this paper, saying that the classical syndrome of this disease was spastic paralysis of the lower extremities, often involving the trunk muscles, occasionally the upper extremities and sometimes the face muscles as well. The muscles of the upper and lower extremities, as in his cases, were hard and resisted passive movements. Reflexes were increased; ankle-clonus and Babinski were commonly present. Pes equinus and adductor contractions occurred. Some patients soon became bedridden, while others might walk for some time. Optic atrophy might occur; as might also weakness of the eye muscles, nystagmus, vertigo, idiocy,

speech defects, bulbar symptoms, atrophy of the small muscles of the hand, bodily defects, hyphosis, and scoliosis. Sensation was normal, and there were usually no involuntaries. He reported three cases of the same parents, in which neither parent was alcoholic or neuritic. They had three other children which did not become affected. The familial characteristics were clearly evidenced in these patients although no definite fault could be discovered in the racial line of either parent.

Dr. JOHN H. W. RHEIN of Philadelphia said that about two years ago before the Philadelphia Pediatric Society he had described a family very much the same as that described by Dr. Riggs. There were five members, all of whom were affected in the same way. One child escaped. All these children had developed the disease in the fourteenth year of age. One of these children had died at the age of 14, after a serious convulsion. The Wassermann reaction of the father and mother of the children had been negative. This was the only generation in which this had occurred. He had looked up the literature and found the disease reported in 111 families by some ninety observers.

On the Diagnosis of Subacute Combined Sclerosis of the Spinal Cord Associated with Severe Anemia.—Dr. WILLIAM B. CADWALADER of Philadelphia read this paper, in which he stated that in 1913 Dejerine had published an article in which he called attention to a certain type of sensory dissociation observed by him in three cases of posterolateral sclerosis of the spinal cord, one of the cases coming to autopsy. The type of combined sclerosis ran a subacute course and had its origin in an infection or a toxic process, the nature of which had not been definitely determined, or was referable to pernicious anemia. The author recorded the notes of the histories and the results of examination of nine cases that he believed conformed to the type of combined sclerosis of the spinal cord associated with anemia. In each of these cases there was more or less disturbance of voluntary motor power of the lower extremities, with ataxia and moderate spasticity. The tendon reflexes were exaggerated, and in all but one the presence of a typical Babinski sign was demonstrated. Two types of sensory phenomena were recorded, subjective and objective. The patients all complained of subjective disturbances of sensation, variously described as numbness, burning, tingling, coldness and heaviness of the lower extremities or of the hands. Examination showed that tactile sensation and sensations for heat, cold, and pain were normal in all but one case. Bone sensation, as tested by the appreciation of the vibrations of a tuning fork, was lost or modified in the lower limbs in every case. The inability to recognize posture of the toes, associated with diminished appreciation of passive movements of the toes or fingers, was present in all cases. It was known that the various deep sensations and stereognostic perceptions passed through only the long fibers of the posterior columns, and it was the long fiber system alone that was involved in this type of combined sclerosis. It was clear, therefore, that by applying these known pathological and physiological facts it was possible in most cases, accurately to determine the location and extent of the sclerosis when it occurred within the posterior columns, and, by determining the location and extent of the sclerosis, a positive opinion as to the nature of the condition that had produced it could be given.

Dr. JAMES J. PUTNAM of Boston said that he was fortunate enough a good many years ago to see eight cases and to have four postmortem examinations in rapid succession and then for many years he took great interest in this very striking trouble. In the first place he was rather surprised that Dr. Cadwalader spoke of a reflex condition, the knee jerks, etc., as exaggerated. That was to say, he spoke of the whole picture as of being of a spastic trouble even in the early stages. Certainly in almost all the cases he had seen, and Dr. Taylor and he at one time reported fifty, that had not been the case, and, whether it was that they missed the early stage, he did not know, but he did not see how that could have been, for he had seen these patients from the very earliest moment. The microscopic changes were certainly very striking. He had seen a very considerable improvement in at least one of these patients through training similar to that one used in tabes.

Dr. C. EUGENE RIGGS of St. Paul said that as to treatment, he had in one or two instances noticed very marked improvement from the intravenous injection of salvarsan. He remembered a patient who had died recently in which he was able to get the blood count up to normal; although the cord symptoms remained the same. The patient left his observation and some time ago died. He presumed there had been a return of the anemic state. He remembered a patient two or three years ago who could not walk. That patient walked in a somewhat unsatisfactory manner when he left the hospital and he had heard of no recurrence of the trouble. Bramwell stated that he had one case of remission in pernicious anemia which lasted nineteen years; therefore he thought the patient still needed watching.

Dr. CHARLES L. DANA of New York City said that this seemed to be a disease which was increasing in this country. Certainly he saw many more cases than he did a few years ago and not long ago he had received a letter from a gentleman in charge of a large sanatorium in the Middle West in which he said, though not a specialist himself, that he had a great many cases of this type coming to his sanatorium. If you saw these cases very early and recognized their character, not necessarily by any distinct evidence of pernicious anemia, for you often don't get that, you could hold them and sometimes keep them well for years. He had a patient of this kind now in the fourth year and distinctly better than when he first saw him. If the cases went on until they were really established, the patients almost always died in two or three years. Hence, it was a matter of extraordinary importance to the neurologists and to the general profession to detect these cases early.

Dr. L. F. BARKER of Baltimore said that in his experience there were two extremes of clinical symptoms. Sometimes the extreme was on the ataxic side, sometimes the spastic side. In other words, sometimes the degeneration was more marked in the lateral funiculi and sometimes in the posterior funiculi. The emphasis on cases occurring without anemia seemed to him important. He believed it made clear that the cord lesion was not due to anemia but that the cord lesion and anemia probably had a common cause. It was a disease of the whole body. There was another factor which should always be kept in mind. None of these patients had acid in the stomach juice. It was a disease, therefore, which probably involved the whole body, a very extensive distribution of lesions and disturbance of function. It looked as though it were a toxic affair. Another point he would emphasize was the occurrence sometimes in families. He remembered distinctly two instances in which two brothers were affected. He had seen the best results from large doses of hydrochloric acid after meals and arsenical preparations internally, through salvarsan, together with a period of rest and general upbuilding. He had one man who had been very well for several years; his hemoglobin had gone to 108 and he was a very robust man. His brother had died. The patient's hemoglobin was down below 30 per cent. at one time. He could not believe he would continue well. He thought he would ultimately die of the disease.

Dr. HUGH T. PATRICK of Chicago, presented this paper, saying that in 1908 Laurans collected nineteen cases of facial diplegia in multiple neuritis. To this list the author has added twenty-nine, including his own, but perhaps two or three of these might be considered doubtful besides half a dozen that he had taken at second hand, the original reports not being accessible. Perhaps the most frequent type was a not very severe multiple neuritis beginning in the legs, affecting the arms less, with total facial diplegia. The combination of complete double facial palsy with less intense involvement of the extremities was the striking feature. In only one rare instance was the facial palsy partial. But the degree of quadriplegia was exceedingly variable. Assuming that multiple neuritis was always caused by a poison and knowing that certain tissues were peculiarly vulnerable to certain poisons, perhaps it was equally reasonable to say that certain poisons had a special predilection for certain tissues. This could not confidently be answered in the affirmative. But the negative aspect was interesting. Apparently the most frequent causes of multiple neuritis did not cause facial diplegia. No case had been due to a metallic poison (except probably one of plumbism) and he believed no case due to alcohol, although one patient had been a wine dealer. He had found no typical case due to diphtheria, though of 171 cases of diphtheritic paralysis collected by Ross, five showed more or less facial diplegia and of fifty cases of precocious palatal paralysis in diphtheria collected by Rolleston, two had had

labial palsy. There was no case following typhoid unless his first case was one. The most frequently surmised cause had been influenza but in no case was the definitely ascertained and in only four out of thirty-four cases was it thought highly probable.

Dr. SIDNEY I. SCHWAB of St. Louis said that he had had two cases, one of which died and the other recovered, in both of which the bladder and rectal reflexes were lost. That brought up two points of particular interest: one was the diagnostic side of these cases, that was the differentiation from so-called myelitic processes and, second, the mechanism of the process itself. It seemed almost a clinical proof, it appeared to him, of the work of Rose, the experimental work in regard to which, through the sheath of the sciatic nerve, material could be carried in certain instances to the spinal canal. He thought the method by which the spinal cord was finally attacked was through the sheath of some of the peripheral nerves. He believed it was impossible anatomically to procure bladder and rectal insufficiency purely through the peripheral mechanism. It was too complicated and there were too many collateral branches and we must conclude that in these cases there was some definite process which got to the cord along the nerves which happen to be attacked. The other feature he happened to know about was the curious emotional state of these patients. The neuritis itself might be somewhat insignificant, but in the midst of this neuritic complication the sudden or even gradual paralysis caused in these patients, at least in two he knew about, a most profound emotional disturbance. The last patient he had became very emotional and very depressed, slightly maniacal, and with the disappearance of the facial diplegia these symptoms disappeared.

Dr. WILLIAM G. SPILLER of Philadelphia said that he might add another case of facial diplegia which occurred in neuritis. He had been interested in alcoholic neuritis. A year or two ago he had had a man in his service with marked neuritis of the Landry type. There had been ascending paralysis. He had had marked diplegia facialis. It was purely alcoholic. He had been admitted to the "drunk" wards many times. In regard to Dr. Patrick's statement regarding the possible toxic factor, during the past winter there had been an interesting case in the Philadelphia Hospital, that of a boy recovering from tetanus. During the latter period he had developed facial paralysis. Facial palsy was fairly common in tetanus. The facial palsy had developed during the fourth or fifth week from a draft. He thought that the tetanus intoxication predisposed the lad to the effect of the draft.

Dr. ARCHIBALD CHURCH of Chicago said that there had been admitted to the neurological service at Michael Reese Hospital last November a young man who presented the condition Dr. Patrick had outlined, rather mild multiple neuritis with diplegia. He had made a searching investigation for the cause of the disease, although the condition had appeared some two weeks before his admission. There had been a most painstaking search of the secretions of the body, spinal fluid, blood and everything else which was open to laboratory investigation, but these had been entirely negative. The causation therefore was obscure, but the boy had been excessively fond of candy, to which he had access, and had eaten one to two pounds a day. After the onset of symptoms, which were largely sensory at first, a severe diarrhea developed. He had recovered rapidly and was discharged in ten weeks able to walk and feeling quite comfortable. Another case he had seen many years ago and which had occurred with acute intestinal disturbance.

Dr. CHARLES L. DANA of New York City said that he had watched cases of neuritis in alcohol wards for twenty-five or thirty years, and there had never occurred a case of facial diplegia. He had been accustomed to look out for that phenomenon because many years ago he had had a case which fell definitely into the group that Dr. Patrick had described. This had been a case of a young man quite well known, a tennis player, very active, athletic and a moderate drinker, who had gone down to North Carolina and, while there, had been exposed to a good deal of cold and wet, possibly canned food, and had developed a slight degree of multiple neuritis and very complete facial diplegia. He had gradually but slowly recovered from his neuritis and almost completely from the diplegia. Dr. Schwab had spoken of the mental state. Rather curiously, though this patient had been somewhat depressed, he had apparently gotten well. About ten years afterward he had developed melancholia and shot himself. He thought the suggestion Dr. Patrick had made that these things were toxic in character was in harmony with what we had been believing in regard to the pathology of paralysis. He had for a long time considered that it was an infectious neuritis and he did not see that the fact that a neuritis was unilateral would exclude infection. We got infectious herpes. It seemed to him that along that line we should discover the cause of the disease.

Dr. SMITH ELY JELLIFFE of New York City asked what lay behind the individual susceptibility in these cases? It certainly was recognized that the toxic factor might be one of the links in the chain, but what about the nervous system itself? What about the variations in the nervous system? What about the condition which Adler had called specific attention to and from that attitude of mind one must interpret the hysterical monoplegia of toxic origin, the diplegic cases of bacterial origin. In such cases one must go to the hysterical side of the mechanism.

Dr. S. LEOPOLD of Philadelphia said that he wished to place on record a similar case in which the etiology was clear. It showed the typical facial diplegic and multiple neuritic phenomena, in which the origin was given as quinsy. It was known that quinsy was associated with streptococci. The etiology might be fairly closely associated.

(*To be continued.*)

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

Stated Meeting, Wednesday, May 3, 1916.

DR. WILLIAM J. TAYLOR, VICE-PRESIDENT, IN THE CHAIR.

Mental Disease and Mental Defect; Their Magnitude and Import.—Dr. OWEN COPP, Physician in Charge, Pennsylvania Hospital for the Insane, observed that it was a common fallacy of the public mind and especially of the mind of the legislator, that mental disease and mental defect might be neglected without serious consequences, which fallacy was grounded upon a deep unconsciousness of the magnitude of the matter. Mental disease, though multiform, affected three classes of individuals: (1) the insane; (2) the feeble-minded, and (3) the epileptic. Percentages taken from the last United States census, while not necessarily signifying a relative increase in the prevalence of insanity, proved the public burden to be increased by accumulation of insane in institutions more than twice as fast as the general population. Figures presented only the average for the whole country, a wide variation obtaining in different States; for example New York had a ratio of 74 per cent. larger than Pennsylvania in institutions, and an admission rate of 59 per cent. in excess of Pennsylvania, while Massachusett's ratios in excess of Pennsylvania's were 75 and 114 respectively. The deficiency of enumeration and provision for the feeble-minded and epileptic was shown to be greater than for the insane. The annual cost of the burden of insanity alone at the conservative estimate of $175 per capita of insane in institutions in 1910 was presented as $32,863,425 in all the States of the Union. This, however, did not show the cost of home care, the loss of income from productive labor, the handicap of the wage earner by a dependent in the family, nor the consequences of stress upon relatives with similar inheritance predisposing to mental breakdown. It ignored also the collateral burden of inefficiency, vagrancy and pauperism, delinquency and crime, of alcohol and drug inebriety and associated evils upon the present generation, to say nothing of the future. Goddard's tragic story of Martin Kallikak illustrated the possibilities of harm to succeeding generations. There should be in the writer's opinion a militant attack upon the whole problem, the first step in advance should be a definition of the problem itself and its exact relations to social and economic conditions. Progress already made by public and private agencies was noted. There was needed in every large community a psychiatric hospital, free to the poor, the center of investigation and diagnosis of mental abnormalities for the guidance of educators, juvenile courts and charitable agencies; for short intensive treatment of acute mental conditions on the plane of the hospital for physical diseases; in affiliation with the medical school and university for clinical teaching of psychiatry and abnormal psychology that the future family physician might be retained to foresee, prevent, and afford early treatment of incipient mental disease; with its outpatient department to facilitate

home treatment through a social service arm reaching out into the community to promote mental hygiene and supervise the after care of the mentally affected restored by treatment in institutions.

Dr. F. X. Dercum emphasized the importance of the practical questions in the field of insanity and called attention to the lack of facilities for the care of the mentally defective. The victory of the therapeutics of insanity was to be gained by an increased knowledge of its pathology, notably of the rôle of the internal secretions and of the autonomic and sympathetic nervous systems. A still greater victory was to be found in the prevention of insanity by physiological and moral living. All causes damaging the germ plasm of the parent impaired the structure and metabolism of the descendants. The rôle of syphilis and alcoholism was obvious.

Dr. George E. Price observed that it was curious that the branch of medicine having to do with the most vital element—reason, had been the slowest in scientific development. It was scarcely more than 100 years since the first attempt at rational care of the insane had been inaugurated. He felt that Dr. Copp in speaking of prevention through education had struck the keynote of the problem. The great mass of people referred to by Dr. Copp, apparently normal, but who are the victims of an unstable nervous system because of poor heredity formed the class to be helped by an understanding of normal living.

Dr. Copp, in closing emphasized the necessity of a mental patient receiving the same study as that given any other form of disease, and as a case in point cited an instance of a young girl who had developed some mental trouble said to be dementia præcox, but in whom by a thorough examination such as would be made in a general hospital juvenile paresis was revealed. The history showed that the father had died of general paresis in a hospital for the insane, that the mother and five brothers were syphilitic. The difference between the hospital attitude toward mental disease and the simple care attitude was observed to be that in the latter, effort ceased with the care of the father; while in the former, the attempt was made to prevent infection and to bring others under treatment. That much could be done for the mental patient was demonstrated in that during the last year 55 per cent of a large admission rate at the Pennsylvania Hospital for the Insane recovered; or, were so far improved that they could live under ordinary conditions of life. Not only was it not humane to neglect the chronic case, but not economical. Partial regeneration of nerve centers and development of dormant energies were possible, thus reducing the cost of care of the patient and contributing materially to his support.

Splenectomy as a Therapeutic Procedure. — Dr. Edward B. Krumbhaar, in an historical outline of splenectomy, said it was one of the oldest abdominal operations of which the profession had definite knowledge. It had undoubtedly been practised by the Greeks and Romans and was continued at rare intervals through the Middle Ages. With the advent of anesthesia and the greater surgical skill of the nineteenth century the use of the operation had been extended to the removal of the chronically diseased organ. In the past three years a more active study of the surgical treatment of certain so-called primary anemias had led to the much wider application of splenectomy, which type of case the paper chiefly dealt with. Diseases in which removal of the enlarged spleen was definitely contraindicated included the various forms of leucemia, malaria, atrophic cirrhosis of the liver, and most cases of tuberculosis and syphilis. Too much emphasis he felt could not be laid upon the necessity of ruling out atypical forms of leucemia before splenectomy was undertaken. The presence of a hemorrhagic diathesis should usually be sufficient to prevent operation, although the repeated hemorrhages from varices, or other mechanical cause, as in Banti's disease, were rather indications for operation than otherwise. In the severer anemias if the bone marrow were found to be aplastic splenectomy should not be attempted. The operation had met with surprising success in Banti's disease, Gaucher's disease, the congenital and acquired forms of hemolytic jaundice, and to a lesser extent pernicious anemia. The cause of improvement or cure in these diseases he said was but little understood and was probably different in different disease. In Banti's disease it was important that the operation should be undertaken before the disease had progressed beyond the first of the three stages. Before undertaking the operation, however, all possible causes for the syndrome presented should be ruled out so far as possible by a complete, but not necessarily prolonged, study of the course of the disease, with frequently repeated blood examinations. From an observation of reported cases it would seem wiser to restrict splenectomy in Gaucher's disease to those cases unusually handicapped by the results of the disease but which were still good surgical risks. The field in which splenectomy had been practised with the greatest success was undoubtedly that of hemolytic jaundice. The most important disease to which splenectomy had been applied, on account of its greater frequency and greater severity, was pernicious anemia. Although it was still too early to promulgate any definite decision upon the value of the operation in this disease it was possible to base views upon substantial evidence; although great improvement might be said to persist in a certain number of cases, in the majority the effect of the operation was to produce a remission. The time of operation and the determination of the case to be subjected to operation were questions which must be decided after the lapse of time and the acquisition of more evidence. The operation had already proved of sufficient value to form the prediction that such an accumulation of evidence would in time be forthcoming.

Dr. Edwin E. Graham asked if Dr. Krumbhaar could give any information upon the difference in the prognosis in the three grades of Banti's disease, as he had distinguished them.

Dr. Krumbhaar, in replying to Dr. Graham, recalled one record in which very good results were found after splenectomy late in the third stage of the disease when the patient was very anemic, and with an advanced degree of cirrhosis and ascites. Further than this he could not say.

Dermatitis Caused By Cosmetics and Wearing Apparel, Particularly Those Containing Paraphenylene Diamin.—Dr. Frank Crozer Knowles observed that it had been only of recent years that dermatitis of the scalp, face, neck, and wrists could be positively ascribed to irritants, the exact formulæ of which were known. In 1901 Mewborn reported a case of severe dermatitis of the face caused by the use of a French hair dye the active principle of which was paraphenylene diamin. Apparently the major portion of hair dyes depended for their action upon this element. The frequency of the eruption from this chemical could be judged from the report in the *Journal of the American Medical Association* of eight cases during the first six months of 1909. Heimann had reported six instances within the last month. The distribution of a dermatitis in the upper third of the face, the swollen eyelids, the vesiculation of the rims of the ears were suggestive of the cause. The reaction frequently occurred several days or even weeks after the last application of the dye. The symptoms of intoxication from paraphenylene diamin and other poisonous aniline dyes, it was said, might be divided into (1) Toxic skin eruptions, dermatitis and urticaria, with great burning and itching; (2) Gastrointestinal symptoms, such as nausea; (3) Nervous symptoms, sleeplessness, dizziness, weakness of the legs, epileptiform attacks, and syncope. In several instances death had resulted and cases had been reported in which retrobulbar neuritis with impairment of central vision and a central scotoma for red and green were observed. Damianos had recorded an instance of chronic poisoning from a hair dye containing this substance used over a considerable period. Paraphenylene diamin was not the only chemical responsible for a dermatitis of the scalp and the contiguous parts; instances had been reported in which resorcin, and "triple extract of heliotrope" had caused a dermatitis. Foerster had reported a case caused by the use of a proprietary mouth wash containing formalin; Heimann, an interesting case in which a dermatitis was caused by the use of a bust developer, the outbreak extending to the extremities, neck and face. Aurantia or hexanitrophenylamin, used in the staining of cheap yellow shoes, might also cause an outbreak of dermatitis. Anilin dyes were often also causal of an eruption. Attention was called to the danger of dermatitis from the use of fur dyed with paraphenylene. The apparent immunity shown by some persons might be explained by the resistance of the individual or the perfection of the dyeing process. Since the hair dye mentioned was prohibited from sale in France, Austria, and Germany its toxic properties could be readily appreciated. Olson had made the reasonable suggestion that if the selling of fur dyed with paraphenylene diamin were not prohibited by law there should be at-

tached a label stating that this dye had been employed. Since the wearing of fur was so universal it was urged that the laity in general should be cognizant of the attendant dangers and physicians constantly on the watch for this etiological factor. As a prophylactic measure it should be recognized that dyed fur should not touch the skin.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

THE UNIVERSITY OF THE STATE OF NEW YORK.

May, 1916.

Answer a total of ten of the questions on each paper, but no more.

ANATOMY.

1. Define the following terms: (a) diploe, (b) epiphysis, (c) medullary cavity, (d) Haversian canal, (e) tuberosity.
2. Give the origin of the muscles inserted in the tuberosities and bicipital groove of the humerus.
3. In what vessel does *each* of the following terminate: (a) lateral sinus (*sinus transversus*), (b) internal saphenous vein (*vena saphena magna*), (c) brachial vein (*vena brachialis*), (d) hepatic vein (*vena hepatica*)?
4. Give the minute anatomy of lung tissue.
5. Name the spinal nerves entering into the formation of plexuses and state the plexus with which each is connected.
6. Name and describe (a) the lobes of the liver, (b) the fissures that divide them.
7. Describe the intercostal arteries and give their relations.
8. Describe the development of the femur, and state when (at what time of life) the epiphyses join the shaft.
9. Describe the endocardium.
10. Describe the spermatic cord (*funiculus spermaticus*).
11. Name *three* layers that are differentiated at the embryonic area in the development of the ovum, and mention the structures developed from each.
12. What is (a) the cauda equina, (b) the foramen of Winslow, (c) the optic thalamus, (d) the trigonum vesicæ, (e) the Eustachian tube?

PHYSIOLOGY.

1. Name the automatic centers located in the medulla oblongata.
2. What is the ratio between the respiration and the pulse? What is the average measurement of the adult male chest in (a) deep expiration, (b) complete inspiration?
3. Name the superficial reflexes. Describe a test that may be applied to ascertain the integrity of *each* of the superficial reflexes.
4. Explain the physiology of the accepted fresh air and dietetic treatment of tuberculosis.
5. Name, in order of importance, the avenues through which the heat of the body is lost.
6. Describe in detail the changes undergone by food in the stomach.
7. Give in pounds the normal quantity of blood in an individual weighing 150 pounds.
8. Name the chemical elements that are constant in the human body.
9. State the function of the secretions of the prostate and Cowper's glands.
10. What changes take place in the composition of the blood as it passes through the kidneys?
11. What are the general functions of fat within the body?
12. Describe the physiology of the contraction of a muscle fiber.

CHEMISTRY.

1. What are the alkali metals? Give the valences and the general characteristics of the alkali metals.
2. Describe iodine giving (a) its occurrence in nature, (b) its properties, (c) its therapeutic uses.
3. What is amyl nitrite?
4. Describe a test for lactic acid in the stomach contents.
5. What are proteins? Where in the body are proteins found? Name the chief proteins.
6. Give a test for (a) glucose in the urine, (b) uric acid in the urine.
7. Define water of crystallization. Distinguish between deliquescence and efflorescence.
8. Describe a method of preparation of hydrogen sulphide. What are the properties of hydrogen sulphide?
9. Differentiate between alloy and amalgam.
10. What is wood alcohol? Give the formula and the properties of wood alcohol.
11. What are fatty acids? Name *three* fatty acids.
12. Give the formula for (a) saltpeter, (b) Chile saltpeter, (c) blue vitriol, (d) green vitriol.

HYGIENE AND SANITATION.

1. What are the first two duties of a physician when called to attend a case of communicable disease?
2. What principles must be observed in the safe storage of rain water for a drinking supply?
3. What features should be considered in locating and constructing a privy on the premises of a village schoolhouse?
4. Give the maximum period of incubation in *each* of the following diseases: (a) smallpox, (b) scarlet fever, (c) whooping cough.
5. What diseases may be conveyed through cow's milk?
6. Give the theory of the application of vaccination against smallpox.
7. Name *five* diseases that may be contracted by eating uncooked meat.
8. What *five* common metallic substances are factors in the production of occupational diseases?
9. Give in detail the method used in the United States for accomplishing the registration of marriages.
10. How may Vincent's angina be positively diagnosed? With what communicable disease is it most frequently confused?
11. What are the purposes for which the Binet-Simon test is employed?
12. What are the two most important factors to be observed in preventing the occurrence of bubonic plague?

SURGERY.

1. Describe gangrene of the foot due to diabetes.
2. Give the symptoms and the surgical treatment of the early stage only of tuberculosis of the hip joint.
3. State *two* effective methods of controlling hemorrhage from the popliteal artery, when without access to surgical instruments.
4. Give the technic of lumbar spinal puncture.
5. Describe the operation of thoracotomy for empyema.
6. Describe a radical operation for epithelioma of the lower lip (omit aseptic technic).
7. Give the clinical picture of an acute osteomyelitis of the tibia.
8. What is the treatment of impacted fracture of the head of the femur?
9. Give the clinical history of a case of chronic appendicitis.
10. Discuss the surgical management of gunshot wound of the abdomen.
11. State the most common form of dislocation of the shoulder, and give Kocher's method of reduction.
12. Describe and diagnose femoral hernia.

ANSWERS.

ANATOMY.

1. *Diploe* is the cancellous tissue found between the outer and inner layers of the flat bones.

Epiphysis is a bony process which was developed separately from the bone and afterwards joined the bone.

Medullary cavity is the hollow part in the center of a long bone, and which contains the marrow.

Haversian canal is the central canal of a Haversian system.

Tuberosity is a non-articular, rough, broad prominence of a bone.

2. To the *greater tuberosity of the humerus*, there are attached, the Supraspinatus (*origin* from Supraspinatus fossa of scapula and supraspinatus fascia), infraspinatus (*origin* from infraspinatus fossa of scapula and infraspinatus fascia), and Teres minor (*origin* from dorsal surface of axillary border of scapula). To the *lesser tuberosity*, the Subscapularis (*origin* from subscapular fossa and axillary border of scapula). To *bicipital groove*, the Latissimus dorsi (*origin* from six lower thoracic vertebræ, lumbar fascia,

crest of ilium, and from lower three or four ribs).

3. The *lateral sinus* terminates in the internal jugular vein; the *internal saphenous vein* terminates in the femoral vein; the *brachial vein* terminates in the axillary vein; the *hepatic vein* terminates in the inferior vena cava.

4. *The structure of the lungs.*—"In the lungs the bronchi branch in a tree-like manner, the final ramifications opening into the pulmonary cells. The larger intrapulmonary bronchi are lined by columnar ciliated epithelium resting on a basement membrance. Lying under this basement membrane are longitudinally disposed elastic fibers with loose connective tissue. More externally is a layer of smooth muscle fibers arranged circularly, the bronchial muscle. External to the bronchial muscle is a fibrous coat containing scattered, irregular plates of hyaline cartilage. The smaller bronchi (bronchioles) have no cartilaginous plates, but their muscular coat is well marked. Each bronchiole leads into a small number (three or four) of wider thin-walled spaces, lined by flattened epithelium, and called atria. Out of each atrium open two or three blind diverticula, each of which is called an infundibulum. The walls of the infundibula are studded with hemispherical sacs known as alveoli, which are lined by flattened, non-nucleated, epithelial cells. Between adjacent alveoli there is a dense network of capillaries, supported by a small amount of fine connective and elastic tissue; the network of capillaries is thus common to the two adjacent air cells, and the blood in the capillaries is separated from the air in the alveoli merely by two thin layers of epithelium. In birds, even the alveolar epithelium appears to be absent, the blood and air being separated solely by the capillary wall."—(Bainbridge and Menzies' *Essentials of Physiology.*)

5. The first four spinal nerves enter into the formation of the *cervical plexus;* the fifth, sixth, seventh, and eighth cervical and the first thoracic nerves enter into the formation of the *brachial plexus;* the first four lumbar nerves enter into the formation of the *lumbar plexus;* the fourth and fifth lumbar, first, second, third, fourth, and fifth sacral, and the coccygeal nerves enter into the formation of the *sacral plexus.*

6. The *lobes of the liver* are: Right lobe, left lobe, lobus quadratus, lobus caudatus, and Spigelian lobe (the last three are subdivisions of the right lobe). The *fissures of the liver* are: Umbilical fissure, fissure for the ductus venosus, transverse fissure, fissure for the gall bladder, and fissure for the inferior vena cava.

"*Right and left lobes* are separated from each other by the umbilical fissure on the under surface, and posteriorly by the fissure of the ductus venosus. The right is the larger, and contains the transverse fissure and fissure for the vena cava; is subdivided into the three following lobes:

"The *lobus quadratus:* bounded by the umbilical and transverse fissures and the fossa of the gall bladder.

"The *lobus Spigelii* is on the posterior surface, and is the projection between fissures for the inferior vena cava and ductus venosus, behind the transverse fissure.

"The *lobus caudatus* connects the preceding lobe with the main mass of the right lobe, and lies behind the transverse fissure.

"The *longitudinal fissure* is occupied by the round ligament, and divides the organ into right and left lobes; it is separated into two parts by its union with the transverse fissure.

"The *anterior* part or *umbilical fissure* contains the remains of the umbilical vein, and lies between the left lobe and the lobus quadratus. The *posterior* part or *fissure of the ductus venosus* lies between the left lobe and the lobus Spigelii, and contains the remains of the ductus venosus.

"The *transverse* or *portal fissure* is placed at right angles to the longitudinal fissure, between the lobus quadratus and the lobus Spigelii, and lodges the hepatic duct, artery, and portal vein, nerves, and lymphatics. The artery lies between the duct in front, and the vein behind.

"The *fissure for the vena cava* is placed obliquely at the posterior margin of the liver, behind the gall bladder, lying between the right lobe and the lobus Spigelii, and separated from the transverse fissure by the lobus caudatus. The hepatic veins enter the vena cava at the bottom of this fissure."—(*Aids to Anatomy.*)

7. "The *superior intercostal* artery arises from upper and back part of the subclavian, behind scalenus anticus, bends backward over pleural dome in front of neck of first rib to first and second intercostal spaces, supplies small branches to cord and deep spinal muscles. On the neck of the first rib, the first intercostal nerve is external, and first thoracic ganglion of sympathetic, internal to artery.

"The *thoracic intercostals* (nine pairs) arise from posterior part of aorta, run transversely outward on bodies of vertebræ, and behind pleura to intercostal spaces. The right ones, crossing over front of spine, supply the bodies of vertebræ and pass behind the esophagus, thoracic duct, and azygos veins. The arteries of both sides are crossed by sympathetic chain and its splanchnic branches. On reaching intercostal spaces, they divide into anterior and posterior branches; the *anterior* branch crosses the space obliquely upward so as to get to lower border of the upper rib near the angle: at first it lies between external intercostal and fascia, subsequently between two intercostal muscles; anastomose with anterior intercostal of internal mammary, thoracic branches of axillary. Above the artery is a companion vein, and below the intercostal nerve. The *posterior* branch passes backward between vertebræ and superior costotransverse ligament, sending inward, *spinal* branch through intervertebral foramen to cord, membranes and body of vertebræ, and backward, *muscular* branch which divides into inner and outer branches to muscles of back. A branch, *the collateral intercostal*, is given off near the angle of the rib, which runs along the upper border of the lower rib. Branches accompany the lateral cutaneous nerves of the thorax from the main trunks of the intercostals. The three lower branches pass forward between muscles of abdominal wall; anastomose with epigastric and phrenic."—(*Aids to Anatomy.*)

8. "*The femur is developed* by *five* centers: one for the shaft, one for each extremity, and one for each trochanter. Of all the long bones, except the clavicle, it is the first to show traces of ossification: this commences in the shaft, at about the seventh week of fetal life, the centers of ossification in the epiphyses appearing in the following order: First, in the lower end of the bone, at the ninth month of fetal life (from this the condyles and tuberosities are formed); in the head at the end of the first year after birth; in the great trochanter, during the fourth year, and in the lesser trochanter, between the thirteenth and fourteenth. The order in which the epiphyses are joined to the shaft is the reverse of that of their appearance: their junction does not commence until after puberty, the lesser trochanter being first joined, then the great, then the head, and, lastly, the inferior extremity (the first in which ossification commenced), which is not united until the twentieth year."—(Gray's *Anatomy.*)

9. "The *endocardium* is a serous membrane that covers the inner surface of the heart. Histologically it consists of two layers, an inner lining of simple squamous epithelial cells (endothelium or mesothelium), and an outer layer composed of connective-tissue fibers, connective-tissue cells, and smooth muscle cells. The endocardium is reflected over the heart valves where the smooth muscle is particularly abundant."—(Hill's *Histology.*)

10. The *spermatic cord* consists of the vas deferens with artery to the vas, spermatic artery, and pampiniform plexus of veins forming spermatic vein above, sympathetic nerves, the cremasteric artery, the genital branch of the genitocrural nerve, lymphatics, together with some areolar tissue; it extends from the internal abdominal ring to the testis, passing in its course along inguinal canal, from which it emerges by the external abdominal ring, and thence in front of the pubes to the scrotum. The vas deferens is placed at the back of the cord.

11. *The three layers of the blastoderm* are: The epiblast, mesoblast, and hypoblast.

From *the epiblast* are derived: The skin, and its appendages (hair, nails), and glands (including the mammary glands); the nervous system (brain, spinal cord, ganglia and nerves); the epithelial parts of the organs of special sense.

From *the mesoblast* are derived: The skeleton, connective tissues, muscles and bones, heart, blood-vessels, lymphatics, and spleen; the urinary and generative organs.

From *the hypoblast* are derived: The epithelial lining of the alimentary canal and its glands; the epithelial lining of the respiratory tract, Eustachian tube, thyroid and thymus.

12. The *cauda equina* is the lower part of the spinal cord, consisting of the roots of many nerves.

The *foramen of Winslow* is a foramen connecting the two sacs of the peritoneum; it is situated behind and below the transverse fissure of the liver.

The *optic thalamus* is one of the basal ganglia of the brain; it forms the side of the third ventricle and part of the floor of the lateral ventricles.

The *trigonum vesicæ* is a triangular surface at the base of the bladder, immediately behind the urethral orifice; it is bounded behind at each angle by the orifice of a ureter.

The *Eustachian tube* is an osteocartilaginous channel connecting the middle ear with the pharynx.

PHYSIOLOGY.

1. The *centers situated in the medulla oblongata* are those for: Respiration, salivary secretion, mastication, sucking, deglutition, speech production, facial expression; it also contains the cardiac and vasomotor centers.

2. The normal respiratory rate is about 18 per minute; the normal pulse rate is about 72 per minute. Hence the ratio between the respiration and pulse is about 1:4. The average measurement of the adult male chest is about 32 to 35 inches, in deep expiration, and about 34 to 38 inches in complete inspiration.

3. *Superficial reflexes.* 1. *Plantar;* elicited by stroking or scratching the sole of the foot, which causes attempts to withdraw the foot from the source of irritation. 2. *Gluteal;* a contraction of the gluteal muscles *en masse* when the buttock is gently pricked or scratched. 3. *Cremasteric;* when the thigh is irritated on its inner surface by grasping, stroking, scratching, etc., the homolateral testicle is distinctly retracted. 4. *Erectile reflex of penis;* produced by gentle friction of the glans penis, especially of the frenum, resulting in turgidity of the organ and erection. Its analogue in the female pertains to the erection of the clitoris. 5. *Abdominal;* consists of a retraction of the anterior abdominal walls when the skin is slightly irritated. 6. *Mammary;* in women, a retraction of the epigastrium when the mammary region is tickled. 7. *Palmar;* corresponding to the plantar, usually less developed than the latter."—(Hall's *Physiology.*)

4. "The *objects of climatic treatment* are to furnish a complete change of environment, to withdraw the patient from the influences under which he contracted the disease, to subject him to a climate which will promote healing in the lungs by increasing the activity of the digestive functions and thus stimulating nutrition, by improving the tone of the nervous and circulatory systems, either by invigoration or protection, and by lessening exposure to secondary infections. Further climatic treatment may have for its object palliation of distressing symptoms in patients whose diseases may not prove fatal for months.

The main *object of dietetic treatment* is to enable the patient to regain his lost weight but not to make him a "flabby, breathless mass of inert fat." A patient who eats and digests well is a patient half-cured. The teeth should receive careful attention and be placed in order at once. The preparation and serving of meals should receive the strictest attention, as the kitchen is the only pharmacy that many patients should know. The meals should be carefully chosen and each planned in relation to the preceding. The physician should carefully scrutinize the diet and lay down broad general rules. It is a wise plan to vary the articles of diet as much as possible, and special dishes on special days of the week should be avoided when possible. The table should be attractively arranged and the food well and quickly served (not quickly eaten). Many patients will eat well if the courses follow one another in rapid succession, whereas if long delays occur cough or fatigue may prevent the eating of the desired amount. To pile up a plate with large amounts and to expect a patient who, especially at first, has little or no desire for food to consume it is a mistake. Repeated helpings until the desired amount is eaten is preferable."—(Lawrason Brown, in Osler's *Modern Medicine.*)

5. *Heat is lost to the body* through the skin, the lungs, and in the urine and feces.

6. In the *stomach* the food is mixed with gastric juice, more thoroughly triturated, moved around the stomach, and finally expelled into the duodenum. In the stomach the proteins are split up into proteoses and peptones by the pepsin of the gastric juice, and certain bacteria are killed by the hydrochloric acid; starches are not affected; fats are split up by a gastric lipase.

7. Formerly the quantity of blood in the body was said to be about one-thirteenth of the body weight. Just now it is said to be about one-twentieth of the body weight. According to the former of these, an individual weighing 150 pounds would have about 11½ pounds of blood; on the latter basis he would have about 7½ pounds of blood.

8. The *chemical elements in the human body* are: Carbon, hydrogen, oxygen, nitrogen, chlorine, sodium, potassium, sulphur, calcium, iron, phosphorus, magnesium, fluorine, iodine, silicon.

9. The function of the secretions of the prostate and Cowper's glands is not understood. These secretions are essential to or aid in maintaining the motility of the spermatozoa; perhaps they render the seminal fluid more fluid and so aid in its ejaculation. According to Dearborn, "the secretion of the prostate seems to preserve the vitality of the spermatozoa, while that of Cowper's gland is a mucus which prevents their too wide dissipation in the vagina."

10. The blood on its passage through the kidneys loses water, salts, urea, carbon dioxide, and extractives.

11. *Functions of fat in the body.*—(1) It helps to maintain and regulate the body heat; (2) it acts as a protection to certain delicate structures; (3) it gives form and roundness to the body; (4) it acts as a reserve substance which the body can draw upon for nutrition in case of emergency; (5) it probably plays a part in the maintenance of the life and nutrition of the cells of the body.

12. To produce contraction of a muscle fiber a certain stimulus is necessary. A nerve impulse is generally the stimulus, but mechanical, chemical, electrical, and thermal stimuli will do as well. The time that elapses between the application of the stimulus and the contraction of the muscle is called the latent period. During contraction the following changes take place in a muscle: (1) It becomes shorter and thicker, but the volume remains the same; (2) it consumes oxygen; (3) it sets free carbon dioxide; (4) it forms sarcolactic acid; (5) it becomes acid in reaction; (6) it becomes more extensible and less elastic; (7) there is an increase in heat production, and consequently a rise of temperature; (8) the electrical reaction becomes relatively negative.

CHEMISTRY.

1. The *alkali metals* are sodium, potassium, lithium, rubidium, and cesium. They have a valence of one. Each of them makes a single chloride, a hydroxide, and one or more oxides. The hydroxides are more or less alkaline and are basic in character.

2. *Iodine* is a solid, occurring in bluish-gray crystalline scales; it has a metallic luster, is volatile, and has a peculiar odor: it is slightly soluble in water, but is very soluble in alcohol, ether, carbon disulphide, and benzene. It is a weak bleaching and oxidizing agent. Iodine is a disinfectant, parasiticide, irritant, and counterirritant.

3. *Amyl nitrite* is a liquid containing $C_5H_{11}NO_2$ and other nitrites.

4. *Test for lactic acid.*—Put three drops of concentrated solution of phenol and three drops of an aqueous solution of ferric chloride in a little water; to this add a little of the filtered gastric contents (after a test meal); if lactic acid is present the blue color turns to a canary-yellow.

5. *Proteins* are nitrogenous organic substances of complex composition and unknown constitution. They are found in every cell and tissue of the body, and are indispensable to the "life" of these cells and tissues. The chief proteins are: Albumins, globulins, nucleoalbumins, histons, protamins, albumoses, peptones, hemoglobins, nucleoproteids, glycoproteids, keratins, collagen.

6. *Test for glucose.*—If albumin is present it should be removed. The urine is then tested for *sugar* as follows: Render the urine strongly alkaline by addition of Na_2CO_3. Divide about 6 c.c. of the alkaline liquid in two test tubes. To one test tube add a very minute quantity of powdered subnitrate of bismuth, to the other as much powdered litharge. Boil the contents of both tubes. The presence of glucose is indicated by a dark or black color of the bismuth powder, the litharge retaining its natural color.

Test for uric acid.—To a few drops of the urine add a little dilute nitric acid and evaporate to dryness; a yellowish-red residue is left; add a little ammonia; a violet color results.

7. *Water of crystallization.*—Many substances, upon assuming the crystalline form, take with them a certain number of molecules of water which are necessary for the maintenance of the form (and often of the color) of the substance. This water is called *water of crystallization.*

A *deliquescent* substance is a solid which has such a tendency to unite with water that it absorbs it from the air, becoming damp and finally liquid.

Efflorescence is the property of certain crystalline bodies whereby, on exposure to air, they lose their water of crystallization and fall to powder.

8. Hydrogen sulphide may be prepared by the action of dilute sulphuric acid upon ferrous sulphide:

$$FeS + H_2SO_4 = FeSO_4 + H_2S.$$

Hydrogen sulphide is a colorless gas with a disgusting odor and taste (like rotten eggs); soluble in alcohol, slightly soluble in water; it is used as a reagent in the chemical laboratory.

9. An *alloy* is a substance composed of two or more metals.

An *amalgam* is an alloy containing mercury.

10. *Wood alcohol* is methyl alcohol, CH_3OH. It is a colorless liquid, with a sharp, burning taste and an alcoholic odor; it burns with a pale flame, giving less heat than that of ethyl alcohol; it is a good solvent for resins, sulphur, potash, and other substances. It is poisonous.

11. *Fatty acids* are monobasic acids, of the acetic series, with the general formula $C_nH_{2n}O_2$. Acetic acid, CH_3COOH; valerianic acid, C_4H_9COOH; palmitic acid, $C_{15}H_{31}COOH$.

12. Saltpeter, KNO_3; Chile saltpeter, $NaNO_3$; blue vitriol, $CuSO_4$; green vitriol, $FeSO_4$.

HYGIENE AND SANITATION.

1. In case of communicable disease, the physician should isolate the patient and inform the local health authorities.

2. "In collecting rain from roofs, it is very necessary to insure cleanliness of the supply, by allowing the first flow to run to waste, thereby avoiding contamination by dirt, leaves, bird-droppings, soot, and other matters deposited upon the roof and collected in the gutters. A number of automatic devices are in use for the purpose of diverting the first washings away from the conductors. After this has been done, they change position, so that the subsequent fall is saved and stored. . . . Cisterns for storage of rain should be so constructed and arranged as to admit of easy inspection and cleaning. They should be kept covered so as to exclude dirt and dust of all kinds, insects, mice, and other animals, and to shut off light as well, for the presence of light is an important aid to the development of lower plant forms. The best materials for their construction are bricks, stone, cement, and slate. Cement makes a good lining if one is desired; mortar, however, is objectionable on account of the solvent power of water upon lime, which will cause progressive increase in hardness. Cisterns should be provided with overflow pipes discharging into the open air rather than into the house sewer, and their exits should be protected by wire netting against the entrance of leaves and small animals." (Harrington's *Hygiene.*)

3. "The *privy* must be at least six feet away from any dwelling, and fifty feet away from any well, spring, or stream; ready means of access must be provided for the scavenger, so that the contents need not be carried through a dwelling; the privy must be roofed to keep out the rain, and be provided with ventilating apertures as near the top as possible; that part of the floor which is not under the seat must not be less than six inches above the level of the adjoining ground and moreover be flagged or paved with hard tiles having an inclination toward the door of the privy of one-half inch to the foot, so that liquids spilt upon it may run down outside and not find their way into the receptacle under the seat; the size or capacity of this receptacle may not exceed eight cubic feet, by which limitation a weekly removal of its contents is necessitated; the sides and floor of this receptacle must be of some impermeable material, the floor being at least three inches above the adjoining ground level; the seat of the privy should be hinged so as to allow of the ashes being readily thrown in, and the receptacle unconnected with any drain or sewer.—(Notter and Firth's *Hygiene.*)

4. The maximum period of incubation of *smallpox* is twenty days; of *scarlet fever* is twelve days; of *whooping cough* is ten days.

5. *Diseases which may be conveyed through cow's milk:* Tuberculosis, typhoid, scarlet fever, diphtheria, measles, foot and mouth disease, milk sickness, cholera, tonsillitis, and gastrointestinal disturbances.

6. *Theory of the application of vaccination against smallpox:* "The more recent view of the immunity conferred by vaccination against smallpox is based upon the demonstration that the disease variola in man and the disease vaccinia in the bovine species are of the same nature and not different, as was formerly believed. This has been established by numerous inoculation experiments. The disease in the cow is a modified form of the human disease. The effect of the passage of the unknown microorganisms through the insusceptible bovine is to diminish the virulence of the germ, that by its subsequent inoculation in man immunity is secured without the profound disturbance which infection with a germ of unmitigated virulence would involve."—(Delafield and Prudden's *Pathology.*)

7. *Five diseases that may be contracted by eating uncooked meat:* Trichinosis, tape worm, echinococcus disease, tuberculosis, anthrax.

8. Lead, zinc, mercury, arsenic, and antimony may produce occupational diseases.

9. It is impossible to answer this question. There is no method used; each State does as it pleases, and in some States there is no law on the subject.

10. *Vincent's angina* may be positively diagnosed by the finding of the fusiform bacillus and the spirocheta darticola in the membrane; it is most frequently confused with diphtheria.

11. The *Binet-Simon test* is employed to test the mentality of children and feebleminded persons.

12. Two most important factors in preventing the occurrence of bubonic plague are: (1) Complete destruction of rats and keeping them out of buildings; (2) persons exposed to infection should receive a prophylactic vaccination with Haffkine's vaccine.

SURGERY.

1. *Diabetic gangrene* "is prone to occur in persons over fifty years of age who suffer from diabetes mellitus. The vessels of these patients are often markedly atheromatous. In some cases the existence of the diabetes is unsuspected before the onset of the gangrene, and it is only on examining the urine that the cause of the condition is discovered. The gangrenous process seldom begins as suddenly as that associated with embolism, and, like senile gangrene, which it may closely simulate in its early stages, it not infrequently begins after a slight injury to one of the toes. It but rarely, however, assumes the dry, shrivelling type, as a rule being attended with swelling, edema, and dusky redness of the foot, and severe pain; the dead part remains warm longer than in other forms of senile gangrene; there is a greater tendency for patches of skin at some distance from the primary seat of disease to become gangrenous, and for the death of tissue to extend upward in the subcutaneous planes, leaving the overlying skin unaffected. The low vitality of the tissues favors the growth of bacteria, and if these gain access the gangrene assumes the characters of the moist type and spreads rapidly. There is usually a peculiarly offensive odor about the patient, which differs from that of other forms of moist gangrene." (Thomson and Miles' *Surgery.*)

2. *The early symptoms of hip-joint disease* are: Night cries (in a child); lameness in the morning; a slight limp; tendency to become tired on slight exertion; wasting; spasm; pain; swelling, and deformity (either real or apparent).

Treatment: In the early stages, rest in bed is indicated, with extension; also, tonics, restoratives, fresh air. If necessary, the limb should be straightened and put up in plaster of Paris, or a brace or other mechanical appliance should be used. Intraarticular injections of iodoform have been recommended. Resection of the hip may be necessary.

3. *Hemorrhage from the popliteal artery* may be controlled by: (1) Placing a pad in the popliteal space and then keeping the leg in forced flexion by means of a bandage; (2) pressure on the femoral artery.

4. *Lumbar puncture:* "The back should be carefully sterilized and through asepsis must be preserved in every detail. The patient may lie on the right side with the left knee well drawn up, may lie prone with a pillow under the belly, or may sit in a chair with the body bent forward. The site of the intended puncture may be frozen with ethyl chloride, but no general anesthetic is required. A Pravaz syringe is employed. The needle, which should be three inches in length, is guarded by the surgeon's index-finger and the point is inserted one-half inch to the right of the median line and between the third and fourth lumbar vertebræ. It is pointed upward and a little inward under a spinous process. In a child the needle enters the canal at a depth of from two to three centimeters; in an adult, at a depth of from four to six centimeters. The fluid is permitted to fall drop after drop into a sterile test-tube." (DaCosta's *Surgery.*)

5. *Empyema.* "Treatment should be undertaken without delay. Aspiration seldom cures, but may be

undertaken where the dyspnea is great, and an anesthetic given afterward for the excision of a piece of rib. Drainage is always necessary, and is best done by excising a portion of the fifth or sixth rib in the midaxillary line. The patient should be allowed to come round quickly from the anesthetic, so that the coughing which occurs will expel the masses of coagulated lymph and help to expand the lung. A big drainage tube is then inserted. Daily dressings are necessary, but irrigation of the cavity is seldom needed." (*Aids to Surgery.*)

6. *The treatment of epithelioma of the lower lip* consists in early and free removal of the affected portion of the lip and of the infected glands. In comparatively small growths which do not involve the angle of the mouth, a V-shaped incision is carried through the entire thickness of the lip so as to include the disease and an area of healthy tissue beyond it. In larger growths, particularly when situated at the angle of the mouth, it is necessary to carry an incision transversely into the cheek to enable the lip to be repaired without leaving deformity. When it is necessary to remove the greater part of the lower lip, the defect may be filled up by flaps of skin taken from below the jaw (Syme's operation). When the tumor is adherent to the lower jaw, it is necessary to resect a portion of that bone along with the lip. The frequency with which recurrence takes place in the lymphatic glands below the jaw renders it advisable to remove these in all cases, whether they are palpably enlarged or not. J. Hutchinson, Jr., recommends that the submaxillary and submental triangles on both sides should be cleared out as a routine procedure." (Thomson and Miles' *Manual of Surgery.*)

7. *Acute infective osteomyelitis.* Causes: The general vitality is lowered, and there is some focus of ulceration in the mouth or throat, by which organisms enter and circulate in the blood. All that is now necessary is that some part of the bone should have its vitality depressed by a blow, strain, or exposure to cold, and the organisms then attack it. The bacteria most commonly found are the staphylococci, but streptococci are present occasionally. The disease usually begins in the new growing bone at the end of the diaphysis, rarely in the epiphysis. The lower ends of the femur and radius, the upper ends of the tibia and humerus, are the commonest seats.

"*Symptoms.*—The disease begins with a rigor, high temperature, and severe pain. The part becomes swollen, infiltrated, and congested, with distended veins over it. The pulse is rapid and small and the tongue dry, and delirium soon comes on. It should be distinguished from acute rheumatism by the fact that the interarticular and not the articular region is affected. Fluctuation can be detected if the bone be superficial, or the abscess may burst on the surface. The bone is then found to be bare over the extent of the abscess cavity. When the bone is deeply seated or the disease confined to the medulla, the swelling is later in evidence, but the pain and toxemia are very severe, and the patient may die from this before local signs show themselves. When the epiphysis is attacked, septic arthritis often quickly follows, and a loose flail joint may result.

"*Treatment* must be very prompt. A free incision must be made through the periosteum and the pus evacuated. In any case, whether pus is found or not, the surface of bone must be gouged away to expose the medulla freely, and any gangrenous tissue scraped out. The cavity must then be washed out and freely drained. The wound in the soft structures is not closed in any part. If symptoms of pyemia occur, it may be necessary to amputate the limb through the joint or bone above, so as to cut off the source of emboli. When a large portion of or the whole diaphysis is necrosed, there are two courses; either to cut short the disease by removing the dead portion at once, or to leave the sequestrum to stimulate the formation of an involucrum. Where there is a single bone, as in the arm and thigh, the sequestrum is left; where there is a double set of bones, as in the forearm and leg, the sequestrum is removed at once. Celluloid, zinc, and ivory rods have been inserted to stimulate osteogenesis. In most cases it is doubtful how much bone is actually dead, so that it is better to open up the cloacæ in the newly formed involucrum to remove the sequestrum. The cavity heals by granulation." (*Aids to Surgery.*)

8. "*In impacted fractures* in the old, liable to break neck close to head, it is unwise to attempt forcible reduction to secure better position of the fragments. These cases should be handled as carefully as possible, and if there are no contraindications the patient should be placed upon a firm level mattress, the foot of the bed slightly elevated, and the leg immobilized either by sand bags placed on both sides or by the application of a long external T-splint. If there is muscular twitching, it is advisable to supplement this dressing by the application of a Buck traction apparatus with from three to six pounds fastened to the stirrup. This weight steadies the part and often gives considerable comfort. This dressing should be used for from four to eight weeks. It may be removed at this time and a short spica of plaster of Paris perhaps applied from the waist to midthigh, and the patient allowed upon crutches. In the aged it is better to remove all apparatus at the end of about five weeks and allow the patient to get up, at first sitting up a short time daily, later resting in a chair, and at the end of about ten weeks walking with crutches.

"Exception to the above rule in the treatment of impacted fractures is in cases occurring in early childhood or middle age, which, if left uncorrected, may result in a deforming coxa vara with considerable subsequent deformity and loss of function. In these cases it is advisable perhaps only after consultation with another surgeon to correct the deformity under ether, place the part in extreme abduction and traction, and while in this corrected position to apply a gypsum spica splint from chest to toes of the affected side after the method of Whitman." (Roberts and Kelly's *Fractures.*)

9. *Chronic appendicitis* may follow an acute attack, but "cases are sometimes met with in which the patient has never had an attack which would suggest acute appendicitis; he complains of impairment of his general health, of abdominal discomfort, sometimes amounting to pain, and inveterate constipation. There may be discomfort in the right side of the abdomen on bending the body or on lifting weights. In some cases the chief complaint is of disturbance of digestion (appendicular dyspepsia). Physical examination is often inconclusive, as there may be no localized tenderness, and nothing can be made out on palpation of the right iliac fossa. The diagnosis is necessarily difficult, and may only be arrived at by a process of exclusion. In many cases it is only cleared up on opening the abdomen, when there is found a kink, stricture, concretion, or twist of the appendix, or adhesions in its neighborhood. Removal of the appendix and liberation of adhesions usually bring about a cure." (Thomson and Miles' *Surgery.*)

10. *Gunshot wound of the abdomen.* "The treatment, even without symptoms of visceral injury, is immediate enlargement of the wound, in order to explore the abdomen, check hemorrhage, and close such visceral perforations as may be found. The abdomen is then flushed with salt solution, and closed or drained, according to the amount of soiling present. If the omentum protrudes it should be ligated and removed, while coils of intestine should be carefully washed with salt solution and returned to the cavity. In cases in which there is doubt as to whether or not a wound enters the peritoneal cavity, such wound should be enlarged and the diagnosis positively made, preparation being made at the same time to treat any visceral injuries that may be found. In gunshot wounds on the battle field an exception has been made to the rule of immediate exploration, because it has been found that the chances of recovery are better without operation."—(Stewart's *Surgery.*)

11. The most common form of dislocation of the shoulder is the subcoracoid. *Kocher's method of reducing* is: To flex the forearm, press the elbow to the side, rotate the arm outward. Bring the arm forward and upward to a right angle with the body, then rotate inward, while the elbow is brought down over the body so that the fingers sweep the opposite shoulder.

12. "A *femoral hernia* protrudes through the crural canal, and presents through the saphenous opening. The coverings are: (1) Skin and subcutaneous tissue, (2) cribriform fascia, (3) anterior layer of the femoral sheath, (4) septum crurale and extraperitoneal fat.

The *Signs* are usually characteristic, viz., a more or less reducible swelling, with an impulse on coughing, and a neck which runs into the abdomen by way of the saphenous opening. From *inguinal hernia* it is distinguished by the neck being below Poupart's ligament and external to the pubic spine. A *psoas abscess* pointing through the saphenous opening is reducible, and has an impulse on coughing; but fluctuation can be felt between the swelling at the saphenous opening and the swelling always present in the iliac fossa in these cases. A *pouch in a varicose saphenous vein* close to the saphenous opening has a characteristic thrill on coughing which should prevent mistakes." (*Aids to Surgery.*)

CLINICAL METHODS OF MEASURING ACIDOSIS.*

BY JOHN R. WILLIAMS, M.D.,

ROCHESTER, N. Y.

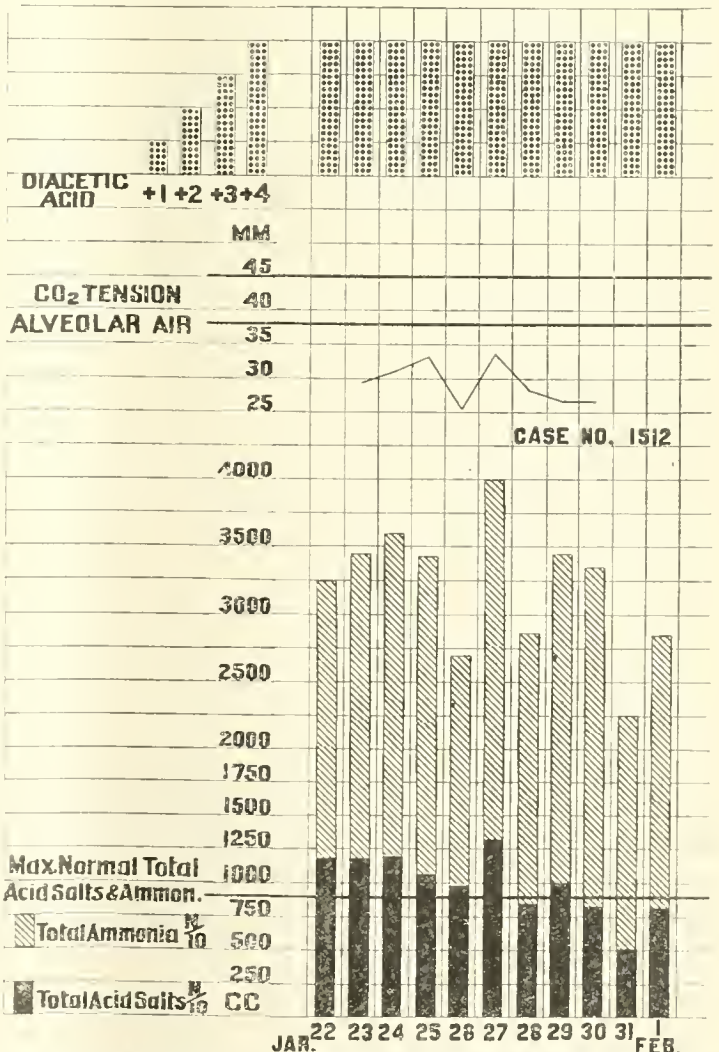
RECENT advances made in medical research have led clinicians to attach greater significance than formerly to the acid content and output of the body. Notably in diabetes and nephritis is it important to have some measure of these facts. The past few years have witnessed the development of several methods of determining with approximate accuracy and reasonable facility the degree or amount of acid intoxication of the body.

A comparative study of the value and limitations of these various methods may be helpful to those clinicians who are not in touch with research or well-equipped clinical laboratories. The phenomenon of acidosis may be estimated either accurately or approximately by the following methods: (1) By a study of the urine in which (*a*) the total acid excretion, (*b*) the total ammonia, and (*c*) the output of ketone bodies have much significance. (2) By a study of the carbon dioxide tension of the alveolar air. (3) By determining the carbon dioxide combining power of the blood. (4) By measuring the hydrogen ion concentration of the blood.

The more practical of these methods will be discussed in detail and illustrated by case records, while the difficult and extremely technical procedures will be but briefly noticed.

The study of the urine, while affording extremely suggestive information, does not necessarily yield a true measure of the body acidity. It tells us only how much acid is excreted. When the production of acid in the body is increased, the outgo in the urine is likewise increased, but there is no definite relationship between the two. Furthermore, there is no simple, accurate way of estimating the total acidity of the urine.

In the metabolism of food and in the tissue changes which accompany work and other energy manifestations, carbonic, sulphuric, phosphoric, oxalic, lactic, hippuric, uric, amino, and other acids are formed. With the exception of the volatile carbonic acid gas, which is eliminated through the lungs, these acids or their various salts, which are non-volatile, are excreted in the urine in varying amounts. According to the laws of physical chemistry, they are dissociated into electrical units, the positive or hydrogen ions and the negative acid radical ions. According to this conception these two sets of ions float about in the solution except when attracted by the poles or electrodes of an electric current. Some acids possess this power of dissociation to a greater degree than do others, hence are known as strong acids, examples of which are sulphuric and hydrochloric acids. Other acids dissociate to a very slight degree and are known as weak acids, examples of which are carbonic and acetic acid. The true acidity of a fluid depends



CASE 1512.—Male. Age, 48 years. Severe diabetes complicated with carbuncle and deep cellulitis in neck, and myocarditis. Operation followed by death from exhaustion without coma. It will be noted that this patient had a severe acidosis evidenced by the excessive excretion of urinary acid and ammonia and by the low carbon dioxide tension.

*Address, in part, before the George Washington Medical Society, Washington, D. C., February 19, 1916.

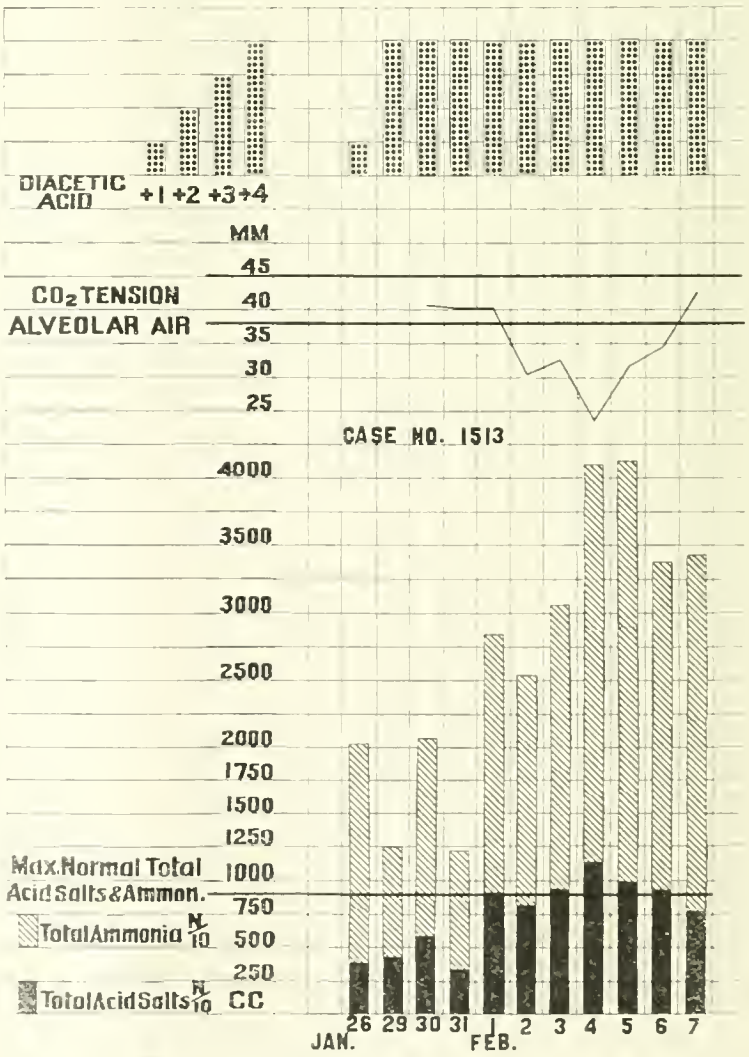
not on the amount of acid but on the amount of hydrogen ions in solution. The measure of these can be determined only by elaborate and extremely technical electrical methods quite beyond the scope of the average clinical laboratory.

The study of the urine by chemical titration methods yields quite different information. By this we determine how much acid hydrogen can be replaced by an alkali or base of definite strength. Thus we attempt to determine the total amount of replaceable hydrogen, which is not the true measure of acidity, for, as above stated, the acidity of a fluid depends upon the amount of dissociated hydrogen ions. Furthermore, in the chemical determination of urine acidity we assume that the turning point from acid or alkali to neutral is definitely revealed by indicators, and this is untrue. No two indicators have the same end-point, hence the determinations by chemical titration means are more or less arbitrary. Notwithstanding these technical difficulties and defects the titration method of estimating urinary acidity is of considerable value when properly done.

The method suggested by Folin is recommended. Decinormal sodium hydrate is used as the alkali and phenolphthalein as the indicator. Neutral potassium oxalate is added to precipitate certain calcium salts which tend to obscure the end-point. It may be done as follows: Place 25 c.c. of urine in a beaker or flask. Add about two teaspoonfuls of finely pulverized neutral potassium oxalate and two drops of a 1 per cent. phenolphthalein solution. Stir or shake vigorously for a few seconds, then titrate with a N10, or decinormal, sodium hydrate solution until a faint but permanent pink appears. Having thus ascertained the number of cubic centimeters of decinormal alkali required to neutralize 25 c.c. of urinary acid, the acidity of the entire 24-hour quantity may be readily calculated. It is better to state this total acidity in terms of decinormal alkali; but, if it is desired to convert it into grams of sodium hydroxide, this may be done by multiplying the total number of cubic centimeters of decinormal alkali by 0.004, the number of grams of sodium hydroxide in 1 c.c. of decinormal solution; or, if it is desired to express it in terms of oxalic acid, multiply by 0.0063, the number of grams of oxalic acid in 1 c.c. decinormal solution.

Having thus neutralized the 25 c.c. of urine, from this same specimen one can easily determine the amount of ammonia present. For clinical purposes, the formalin titration method is sufficiently accurate. This is done as follows: To the 25 c.c. of neutralized urine add 10 c.c. of neutral 40 per cent. formalin. Then titrate again with decinormal alkali. This reading will represent the number of cubic centimeters of decinormal ammonia in the 25 c.c. of urine, from which the amount in the 24-hour specimen may be estimated. The acidity of the urine and that represented by the ammonia are additive. Their sum gives the most accurate expression of titratable urinary acid excretion. For purposes of clinical research Folin's method of estimating ammonia should be employed.

In a preceding paragraph it was mentioned that in the body metabolism two types of acid, volatile and non-volatile, are formed, and that the former is eliminated through the lungs while the latter is excreted by the kidneys. The amount of volatile acid or carbonic acid in the blood bears a constant relationship to the non-volatile acid present. It has been established that the acid content of the body remains practically constant even in the presence of increased production, and that death will supervene before a measurable increase occurs. The body protects itself against this increased production by withdrawing bases or alkali from the tissues, by a remarkable physiochemical property of combining the newly formed acid with neutral salts and proteins in the blood in such way that these substances still remain neutral, by the formation of ammonia from neutral substances, that is the breaking down of proteins, and further by diminishing the amount of carbonic acid in the blood by increased ventilation of it through the lungs. It follows that if the acidity of the blood is repre-

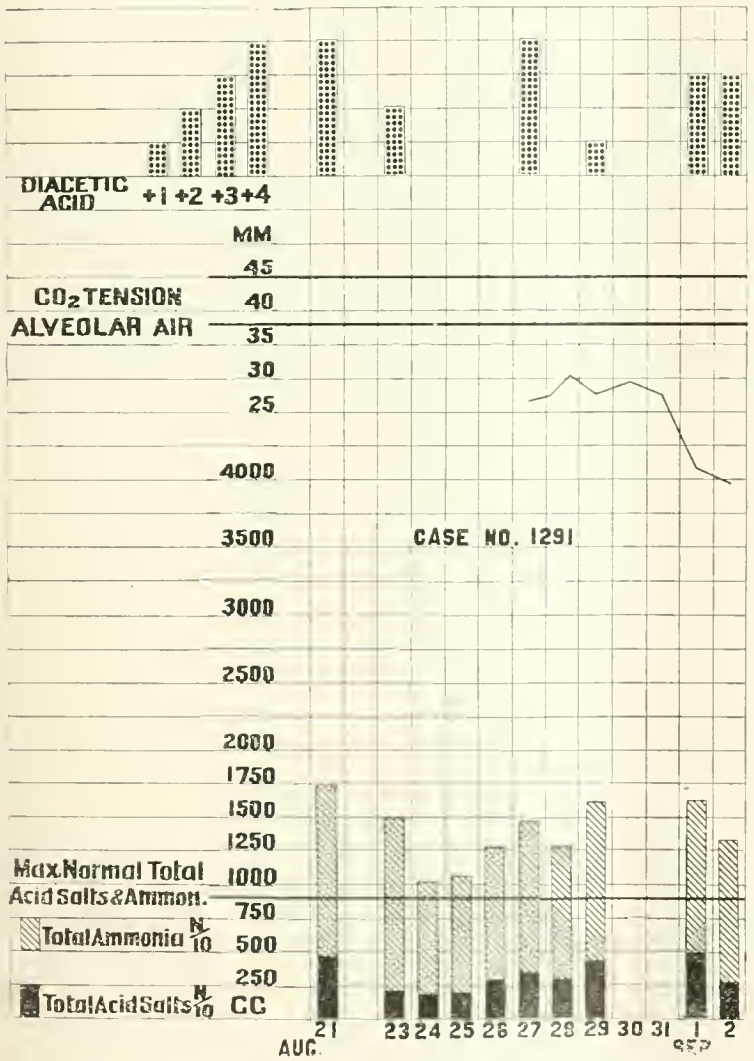


Case 1513.—Male. Age, 74 years. Severe diabetes complicated by advanced arteriosclerosis and gangrene. Operation. Ether anesthesia. Death from exhaustion and without coma. For four days after operation patient exhibited only a mild acidosis, as will be seen from the carbon dioxide tension and urine acid and ammonia output. Following this a severe acidosis developed. The administration of copious doses of soda, water, etc., raised the carbon dioxide tension to practically normal limits two days before death. This case illustrates tremendous acid production with the body eliminating it chiefly as urinary acid. If acid had been retained by the body on the two days preceding death, a much lower carbon dioxide tension would be expected.

sented by the sum of its volatile carbonic acid content and the various other non-volatile acids, that a determination of one enables us to estimate the other; furthermore, if the sum of the two remains constant and one increases in amount, the other must correspondingly diminish. Therefore, a low per cent. of carbonic acid in the blood means a high per cent. of non-volatile acid; conversely, when the non-volatile acids are diminished the carbonic acid content is increased. These facts may be directly ascertained by a determination of the carbon dioxide combining power of the blood, using the unpublished method of Van Slyke, or by taking advantage of the fact that the percentage of carbon dioxide in the lung air is practically the same as that in the arterial blood and employing the much simpler and more practical test of estimating the percentage and barometric tension of carbonic acid gas in the lung air.

Fredericia's Method for Determining the Carbonic Acid Tension of the Lung Air.—Numerous methods for determining the carbon dioxide tension of the lung air have been suggested, but for one reason or another most of them are too complicated or difficult for practical clinical work. The chief objection to many of the methods that have been proposed is that two sets of apparatus are required, one for the collection of the air sample, the other for its analysis. Fredericia's* apparatus was designed to overcome this objection, and his instrument may be used for both purposes. The apparatus, as will be seen from the accompanying cut, is essentially a U-shaped gas-collecting tube, with stop cocks so arranged that a sample of air may be confined in one portion of it and subjected to such chemical treatment as is desired.

The tube is so constructed that that portion of it from stop cock *C*, when closed, to and including the bore of stop cock *G* contains 100 c.c. The section of the tube from *F* to *E* is graduated in tenths of 1 per cent of the total volume of this part of the gas chamber. The scale reads from 2 to 8 per cent. Stop cock *C* is of straight bore, as is seen in the illustrations. Stop cock *G* is of three-way bore. In one position, one arm of the tube communicates with the other; in a second position, communication between the arms is closed; in a third position, the bulb portion of the tube is closed while the other arm communicates with the outlet tube; in a fourth position, these are reversed and the bulb portion communicates with the outlet and the other arm is sealed.



CASE 1291.—Female. Age, 30 years. Acidosis of severe diabetes, fatal. Patient had been fasted for 72 hours preceding Aug. 21. For 48 hours she had been vomiting almost constantly. Aug. 21 had severe diaphragmatic pain, slight air hunger and drowsiness. Aug. 23, more deeply comatose. Difficult to swallow. Note that urinary acid, diacetic acid, and ammonia excretion very small, indicating retention. Aug. 24, 25, 26, 27 patient given 140+ grams carbohydrate, chiefly levulose, daily. Comatose symptoms less severe. Note marked acid retention. Aug. 28 to Sept. 2. Note the very small acid and ammonia excretion compared with the low carbon dioxide tension, and that the ferric chloride test was practically negative on Aug. 28, 29, although patient was quite comatose. Urine not examined Aug. 30, 31.

In carrying out the test the following apparatus and reagents are required: (*a*) the Fredericia gas tube, (*b*) a large glass cylinder of sufficient capacity to hold the gas tube (a stock battery jar 21 x 30 c.mm. is admirably suited for the purpose) (*c*) an ordinary 100 c.c. laboratory wash bottle filled with (*d*) a 5 per cent. solution of sodium hydrate and a 1 per cent. solution of acetic or a saturate solution of boric acid.

Before making the test, the battery jar or cylinder should be filled with water at the temperature of the room; greater uniformity of readings may be had if water at a temperature of 20° C. or 68° F. be used. The purpose of the water is to cool to a constant temperature the gas or lung air of the patient after it has been collected in the tube. This is very important, because the volume of gas varies inversely with its temperature. Each variation of 1° in temperature will cause a variation of 0.4 per cent. in the volume of the carbonic acid.

The person whose lung air is to be examined should sit quietly in a chair and breathe in a natural manner for several minutes. Observations should be made in either a sitting or lying position, preferably the former, as readings vary slightly with the posture of the body. At the end of a normal expiration the mouthpiece of the apparatus (A) is put in the patient's mouth. The stop cocks should be arranged as in Fig. 1. The patient is instructed to expel through the tube as much as possible of the air remaining in his lung, without first talking, coughing, inhaling, or exhaling air.

*Fredericia: A Clinical Method for the Determination of Carbonic Acid Expansion in Lung Air. *Berl. klin. Wochenschr.*, July 6, 1914, pp. 1268-1271.

Most people will thus expel during such an expiration approximately 1500 c.c. of air of which at least 1000 c.c. is alveolar air. Inasmuch as the apparatus contains only about 130 c.c. it will be

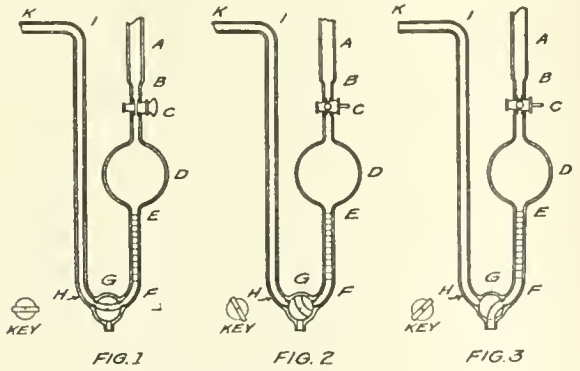


FIG. 1—Showing Fredericia apparatus and the position of the stop cocks at different stages of the test.

seen that the air which is recovered at the end of the expiration will be a representative sample of the air from the lung alveoli. Immediately after the close of this forced expiration and before removal of the instrument from the patient's mouth, stop cock *C* must be closed and remain closed until the end of the test. Stop cock *G*, however, must remain for the present in the same position as in Fig. 1.

The apparatus* is now immersed for from 3 to 5 minutes in the water in the glass jar. The water must extend over stop cock *C*, but must not reach tube *K*. The gas is thus cooled and contracts. For this reason a small amount of air enters the tube at *K* but it does not reach that portion of the tube containing the air to be examined so the result is not affected. The apparatus is then removed and the sodium hydrate solution in the wash bottle is forced into the tube at *K* until the column of liquid in *HK* is on a level with the top of the bulb in the other arm. Stop cock *G* is then closed as in Fig. 2. A small amount of the fluid will have entered the bulb portion of the tube. The apparatus is then tipped, turned, and gently shaken so as to bring the sodium hydrate solution in contact with all parts of the bulb portion, and the carbonic acid contained therein which it absorbs. Stop cock *G* is then opened again as in Fig. 1 so as to allow more sodium hydrate to enter the bulb arm, the stop cock is then closed and the process of shaking repeated. This operation is repeated several times until the sodium hydrate solution will absorb no more gas, which is readily told when the liquid ceases to rise in the bulb arm. The apparatus is once more immersed in the jar of water to restore the gas to a constant

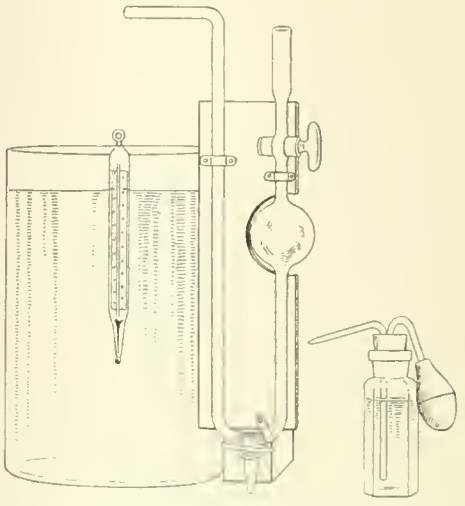

FIG. 2—Showing Fredericia tube and other apparatus needed for the lung air test

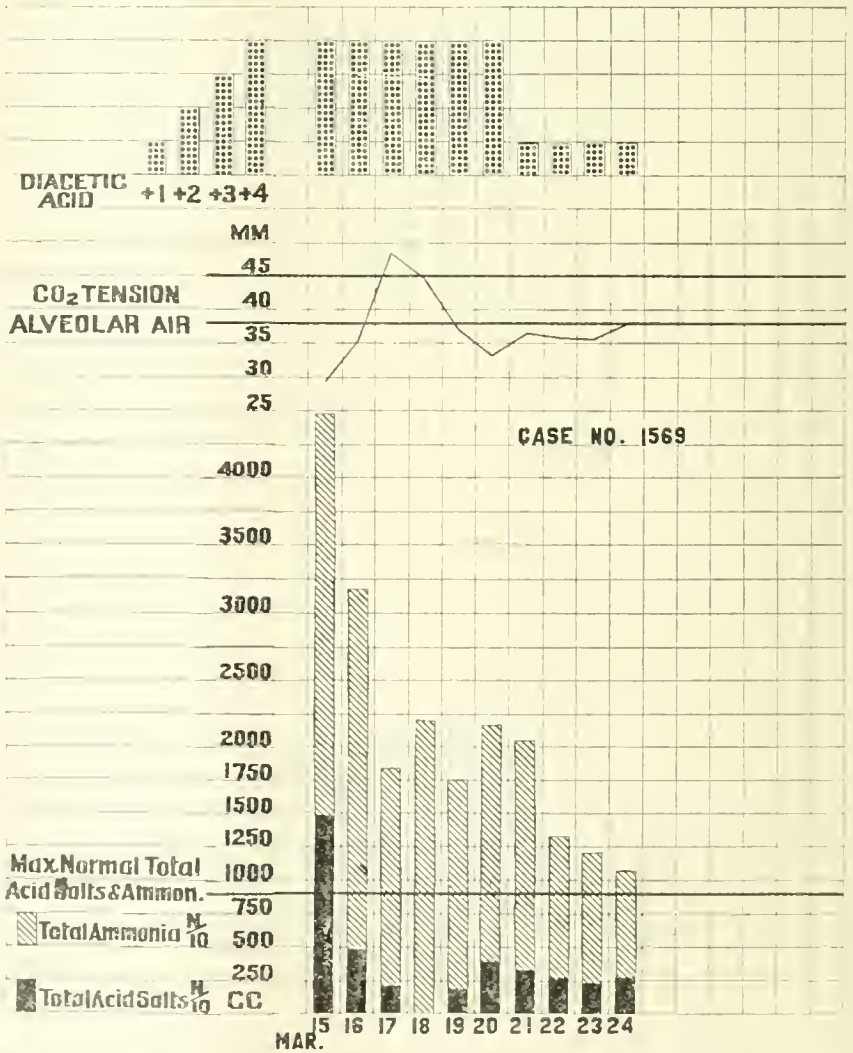
temperature and it should be left therein for at least three minutes. It should then be quickly re-

*Apparatus made by Emil Greiver Company, New York City.



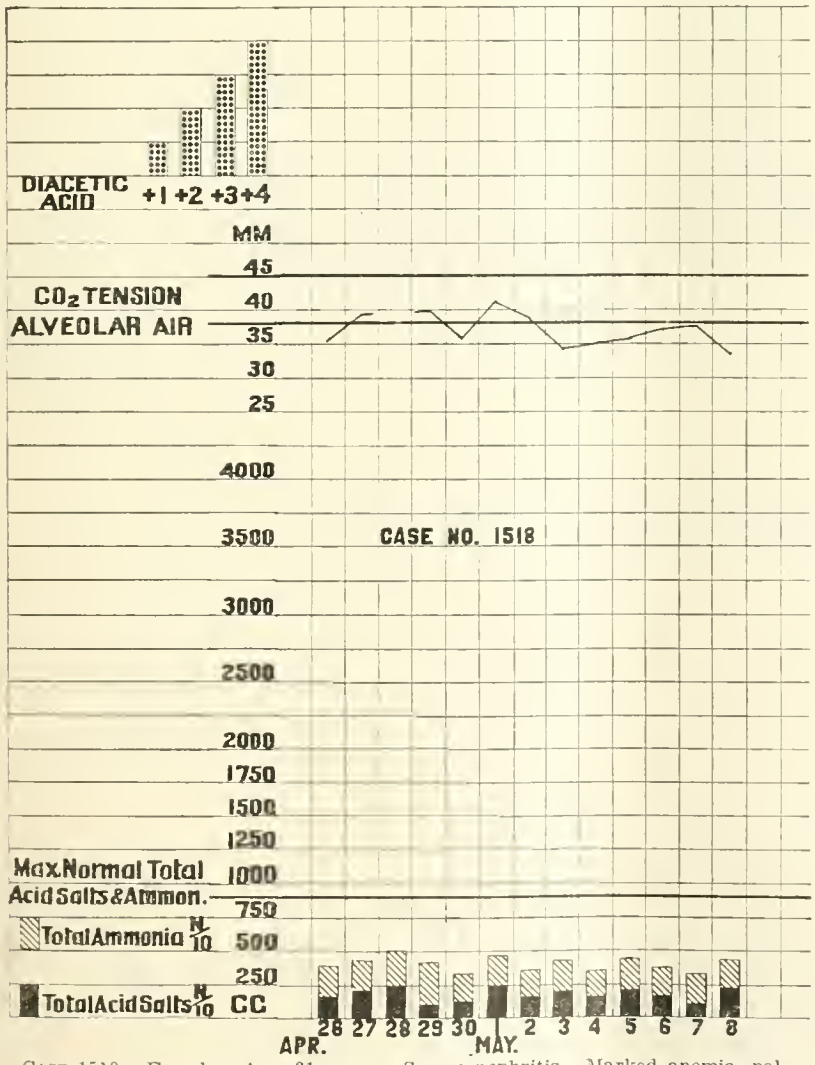
CASE 1569. Female. Age, 31 years. Acidosis of severe acute diabetes. Recovery. Before admission to hospital patient had vomited frequently for 48 hours. On March 15 had severe diaphragmatic pain, air hunger, and drowsiness. Loss of fluids from body probably was chief cause of severe symptoms. Note the greatly increased excretion of urinary acid and ammonia on March 15 and 16, brought about by the administration of large amounts of fluid and alkali, and the beneficial effect of this evidenced by the rise in the carbon dioxide tension.

moved and stop cock *G* so turned as to drain tube *HK*, or as shown in Fig. 3. In this way the liquid in *HK* should be brought down to the same level as in the bulb arm. The apparatus should again be immersed in water for a minute or two, and the leveling process repeated if the column in *HK* is higher than in the bulb arm. The apparatus should then be returned to the glass jar and the height of the column of liquid in the bulb should be read, the observer looking through the jar. The height of this column represents, in cubic centimeters or per cent., the amount of carbonic acid that was abstracted from 100 c.c. of alveolar air at a temperature of 20° C. It has been established that the percentage of carbonic acid in the alveolar air closely approximates that in the arterial blood.

The percentage of gas dissolved in a liquid depends not on the amount present but upon the barometric pressure, hence it is necessary to determine the pressure of that portion of the alveolar air which was carbonic acid gas. If a given per cent. of the lung air is carbonic acid then that per cent. of the barometric pressure represents the tension of the carbonic acid gas. If a sample of lung air contained 5 per cent. of gas and the barometer at the time read 29.0 in. or 760 mm., then the tension of the gas would be 0.05 of 760 mm. or 38 mm. less a slight correction for water vapor. The table on page 229, prepared by Dr. Edgar Stillman in which is shown the tension of different percentages of carbonic acid gas at various barometric pressures, will facilitate the test.

Certain precautions should be exercised in making the lung air test. The apparatus should be clean and dry, because water absorbs its own volume of carbon dioxide. The apparatus should be inserted in the mouth at the end of a normal expiration. If the patient takes a full breath before making the test, as beginners are apt to do, the alveolar air will be diluted by the deeply inspired air and the carbon dioxide output will be appreciably reduced. This is illustrated in Table No. 1.

Explanation of Charts.—These are records of cases exhibiting severe acidosis. They are plotted so that the daily excretion of diacetic acid, total urine acid, and total ammonia, may be compared with the carbon dioxide tension of the lung air. Of these methods the carbon dioxide tension is the most reliable index of acidosis. This is plotted in millimeters of mercury barometric pressure. The commonly accepted normal limits are from 38 to 45 mm. Diacetic acid is estimated by the usual approximative quantitative, ferric chloride method, in which varying intensities of the test are represented by from one to four plus marks. The total urine acid and ammonia are both plotted in terms of decinormal alkali, as will be seen by the key. These two excretory products are additive, therefore one is superimposed on the other. Together they afford a very reliable measure of titratable urine acid excretion. The normal individual rarely excretes more than the equivalent of 900 c.c. of decinormal alkali daily.



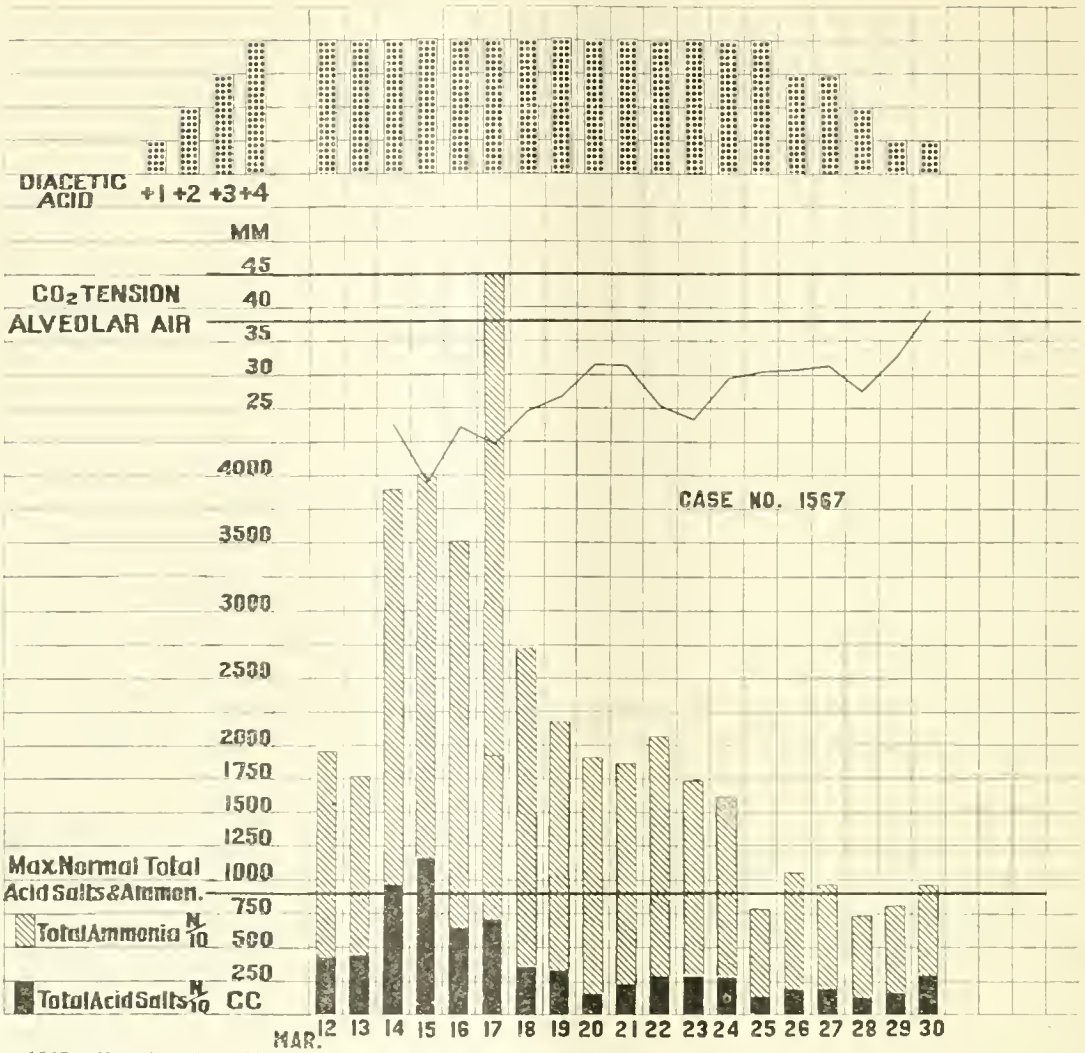
CASE 1518.—Female. Age, 21 years. Severe nephritis. Marked anemia, pallor, and general edema. Kidney function, three phenol-sulphonephthalein, two hour tests. (1) 11 per cent., (2) 20 per cent., (3) 13 per cent. Chloride retention. Systolic blood pressure ranges between 155 and 180 mm. No dyspnea except on exertion. Note the low urinary acid output and slight evidence of acidosis in the carbon dioxide tension.

It is not the purpose of the author to discuss the treatment of the terminal stages of diabetes, but rather to present the measurable phenomena of severe acidosis, and a comparison of the best practical methods of study.

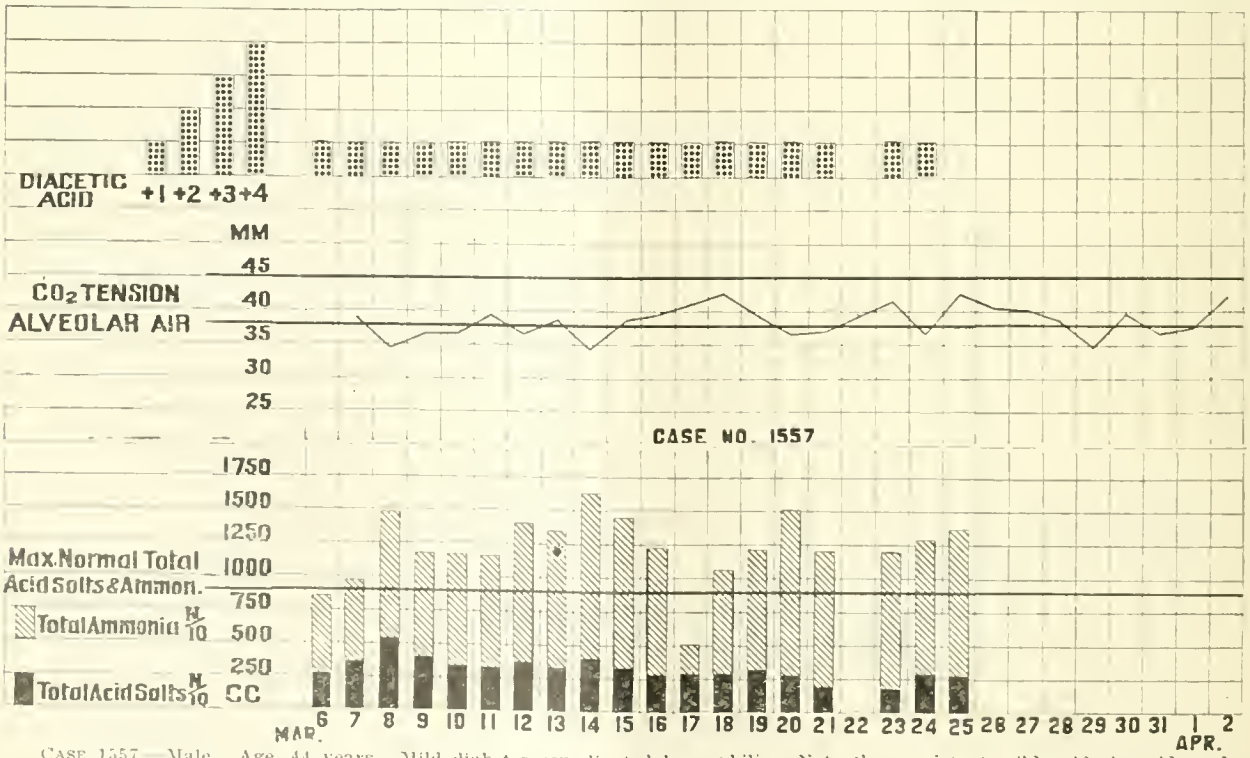
CASE 1641.—Female, Age, 60 years. Patient was found unconscious by family physician. Coma of acidosis was suspected. A lung air test was made in the manner above described and 5.2 per cent. of carbon dioxide or 36.8 mm. tension was obtained. This tended to exclude coma of acidosis. Later it was discovered that patient was unconscious from overdoses of veronal.

CASE 1587.—Female. Age, 44 years. Gastrojejunostomy. Persistent vomiting. For 12 days patient did not receive or tolerate more than 200 calories of food daily. For 48 hours semi-comatose. Compulsory lung air test made. The carbon dioxide equaled 2.3 per cent., or 17.4 mm. tension. Patient died in coma, due probably to acidosis of starvation and exhaustion.

CASE 1568.—Female, Age, 35 years. Primipara, 8 months pregnant. Intense headache and vomiting. Patient conscious. Lung air test made in usual manner. Carbon dioxide equaled 4.4 per cent., or 32.4 mm. tension, suggesting severe acidosis of eclampsia. Two hours later there followed the severe convulsions of puerperal eclampsia. Uterus emptied. Recov-



Case 1567.—Female. Age, 20 years. Severe diabetes complicated by acute appendicitis and marked lipoidemia. Patient exhibited all the early stages of coma, as vomiting, diaphragmatic pain, air hunger, and drowsiness, from March 13 to March 18. Note the striking relationship of excessive urinary acid and ammonia output with the low carbon dioxide tension of lung air; also that the ordinary ferric chloride test affords only a crude index of the severity of acidosis.



Case 1557.—Male. Age, 44 years. Mild diabetes complicated by syphilis. Note the persistent mild acidosis evidenced by the constant presence of diacetic acid in the urine and by the slightly excessive urinary acid and ammonia output. It will be observed that these all become normal when antisyphilitic treatment was begun on March 26.

ery of both mother and child. One week later lung air carbon dioxide was 5.6%, or 40.7 mm. tension.

TABLE FOR THE CONVERSION OF THE PERCENTAGES OF CARBONIC ACID GAS IN THE LUNG AIR INTO TERMS OF BAROMETRIC PRESSURE OR TENSION

Percentage Carbonic Acid Gas	730 Mm. 28.7 In.	740 Mm 29.1 In.	750 Mm. 29.5 In.	760 Mm. 29.8 In.	770 Mm. 30.3 In.	780 Mm. 30.7 In.	790 Mm. 31.1 In.

Summary and Conclusions.—The tests described in this paper can be carried out by any well trained physician. They are simple, require very little time, are fairly accurate, and afford information of much value in cases of severe metabolic disturbance.

TABLE NO. 1.

Comparing the carbon dioxide in the lung air after a normal expiration with the exhalation following a forced inspiration.

Subject	CO_2 After Normal Expiration.		CO_2 After Forced Inspiration.	
	Per Cent.	Tension.	Per Cent.	Tension.
A	7 2	54 7	5 9	42 6
A	7 2	54 7	6 0	43 6
A	7 2	54 7	5 9	42 6
B	7 2	54 7	6 2	44 6
C	7 2	52 2	5 9	42 9

TABLE NO. 2.

Showing the percentage of carbon dioxide and barometric tension of the lung air in a series of normal individuals.

Subject	Age	First Observation		Second Observation	
		Per Cent.	Tension.	Per Cent.	Tension.
Girl	8	6 0	44 0	5 1	37 1
Boy	5½	5 9	42 5	6 0	44 0
Girl	4	5 4	39 8	5 0	36 4
Man	32	6 2	45 5		
Man	28	6 4	47 1		
Woman	28	5 4	39 3		

Comments.—It will be observed that the carbon dioxide tension of the lung air of normal individuals may vary from 36 to 60 mm. Readings in children are practically the same as in adults.

The measure of the urinary acid and ammonia excretion may throw light on the acid production, elimination, or retention by the body. If the urinary acid output is high, production must be high. If low, there may be retention or defective elimination by the kidneys.

TABLE NO. 3.

Showing the effect on the carbon dioxide output of the lung air of compulsory breathing through the tube in a series of normal individuals.

Subject	Normal.		One Minute.		Two Minutes.	
	Per Cent	Tension.	Per Cent.	Tension.	Per Cent.	Tension.
Man (41 yrs.)	8 0	60 8	6 3	45.8	7 8	59 2
Man (41 yrs.)	7.1	53.9	5 5	40 0	7 0	53 2
Woman (28 yrs.)	5 4	39 3	6 3	45 2	5 6	40 7
Girl (6 yrs.)	5 1	37 1			5 3	38 5
Woman (40 yrs.)	7 2	52 2	6 7	48 7	7 5	57 0

Conditions of test.—Subject sitting quietly in chair, air tube in mouth with lips closed tightly about it. Nose pinched shut. Sample of air taken at end of exhalation at end of time limit.

Comments.—It will be observed that when compared with the normal output, the lung air obtained in the Fredericia tube at the end of 1 minute's compulsory breathing contains less carbon dioxide, but that at the end of 2 minutes the readings are practically the same. Therefore the Fredericia used in this way affords a fairly accurate measure of the carbon dioxide tension. This method may be useful when dealing with patients who cannot or will not assist in performing the test in the normal or previously described manner. Thus in stuporous or comatose patients a fairly accurate reading may be obtained by forcibly holding the apparatus in the patient's mouth, at the same time pinching the nose and compelling him to breathe through the tube for two minutes. The following cases seen in consultation illustrate the usefulness of the test when employed this way:

If acid production is high, and there is good elimination, the carbon dioxide tension of the lung air may be high, indicating that the body is protecting itself by kidney elimination alone. If the carbon dioxide tension is low with high urinary acid elimination, it suggests a more profound acidosis for which the body is trying to compensate by lung ventilation. If urinary acid elimination is low and the carbon dioxide tension is also low, increased acid production and retention are suggested and an acidosis and coma of grave prognosis are likely to follow.

The ordinary tests for diacetic acid are of much less value to the clinician than are the urinary acid and ammonia determinations taken in conjunction with the carbon dioxide tension of the lung air. In the experience of the writer these tests are of greater value in diabetes than in other metabolic disturbances or diseases.

In the preparation of this paper the studies of Higgins, Peabody, Henderson, Stillman, and Fredericia have been freely used.

CONNECTICUT, A STUDENT OF TUBERCULOSIS.*

BY STEPHEN J. MAHER, M.D.,

NEW HAVEN, CONN.

CHAIRMAN STATE TUBERCULOSIS COMMISSION OF CONNECTICUT.

SOME years ago, as a member of the State Tuberculosis Commission, I wrote a rather widely circulated paper on "Connecticut, a Doctor of Consumptives." In that paper I told of Connecticut's method of treating the three hundred patients in her three tuberculosis santaoria. Since then Connecticut's practice as a tuberculosis specialist has increased considerably. She now has four tuberculosis sanatoria and every day she treats more than five hundred tuberculous patients. If she could afford it she would have even more patients. We who have had charge of this practice of hers have long recognized that although in giv-

*Read before the Meriden Medical Society, April 27, 1916, and in part before the Stamford Medical Society, February 19, 1916.

ing to these five hundred patients the modern hygienic dietetic treatment of the disease we were doing justice to the patients, we were not doing entire justice to Connecticut. Why not? Because justice to Connecticut demanded that we not only treat these patients but that we study them to such purpose that in the future there should be less tuberculosis in Connecticut.

We realized that, like the rest of the world, we were unable to answer many of the important questions that hover like Zeppelins over our present theory of tuberculosis. Of course, many of the enthusiastic leaders of the anti-tuberculosis campaign deny the importance of the questions and profess to see no threatening shadows or shapes in the clouds that pass over the trenches of the anti-tuberculosis armies. But most physicians, and even the laymen who have given the subject proper study, realize that tuberculosis is still a mysterious disease, and that we must conquer the mystery before we will be able to conquer the disease.

Now where could there be better opportunities for attacking both the mystery and the disease than in our State sanatoria? In these sanatoria are more than five hundred patients, in all stages of the disease, drawn from the million or so of people who look to Heaven from the comparatively few square miles of Connecticut. In these sanatoria are good physicians and nurses, good microscopes, and a sufficient, if small, laboratory equipment.

"Then why not do some scientific research work?" That is the question we have been asking the superintendents of the various sanatoria for some years. "You know the great need of this research work. You have the ability, have you not? You have the material and the instruments. And we promise you public recognition of any good work that you may do."

Several of the physicians responded to our appeal by making a few rather desultory and incomplete experiments, but nothing satisfactory was accomplished until 1915.

In March of last year the commission voted to hold a medical conference once a month at one of the State sanatoria, and to require the medical staff of the sanatorium at which the conference was held to be ready at the conference to present to the commission and to the physicians of the other sanatoria some interesting new work or some studies of the especially interesting cases in the institution. It is only a year since this rule went into effect, but it has already worked wonders. The superintendents and their assistant physicians have taken up the idea with the heartiest enthusiasm. A rivalry, keen but friendly, has developed between the four institutions for the credit of having the best conference. I must confess that I have been astonished at the fine quality of many of the papers and demonstrations. Some of the conferences were good enough to command the time and attention of the best doctors anywhere. Here are a few of the topics. Of course, I will not go into enough details to spoil the publication value of the original work.

1. At the Hartford Sanatorium, Dr. Wagner gave interesting *x*-ray demonstrations of many of the difficult cases, and thus brought up for discussion the whole subject of *x*-ray diagnosis in tuberculosis. He also applied the luetin test to 160 patients in the sanatorium. He found that an astonishingly large proportion of the patients gave a positive reaction, but the results, as was brought out in a sharp general discussion, were largely nullified because of the fact that most of the patients had received iodine medication within a few days or weeks of the test. Nevertheless, his report of the reactions and his searchings of the patients' bodies and histories for stigmata of syphilis were very stimulating and did much to increase the interest of all of us in the question of the frequent coincidence of the two diseases, syphilis and tuberculosis.

At the Hartford Sanatorium, Dr. Strobel presented a most interesting study of the possible relation of the pneumococcus to hemoptysis in pulmonary tuberculosis. He isolated from the bloody sputum of all of a short series of cases of pulmonary hemorrhage a typical pneumococcus which was pathogenic to rabbits. He is still at work on this problem.

2. At the Norwich Sanatorium, Dr. Campbell and Dr. Lynch have demonstrated that the preliminary injection of guinea pigs with a very slightly virulent type of the human tubercle bacillus, did not interfere in any way with the action of a highly pathogenic strain of human tubercle bacilli injected after some months into these same guinea pigs. They died at exactly the same time as the controls.

Dr. Lynch also presented a study of the bacterial findings in the mouths of fifty consumptives in the later stages of the disease. In only four of the cases could he demonstrate tubercle bacilli in the wipings or washings of the teeth, gums, tongue, tonsils, or pharynx. These four cases were all in extremis and were all dead within ten days of the examinations. Other subjects presented at the Norwich Sanatorium conference were: "The Source of the Infection in Tuberculosis," by Dr. Campbell, and "The Pre-Bacillary Forms of the Tubercle Bacillus," by Dr. Lynch.

3. At the Meriden Sanatorium, Dr. Dinnan has carried out two interesting bits of work. One concerned the question of heliotherapy. Of course, everybody knows that sunlight properly applied benefits patients suffering from bone or glandular tuberculosis, but the question of whether the continued exposure of the skin of all the body to the direct rays of the sun benefits cases of pulmonary tuberculosis has not been satisfactorily answered. Dr. Dinnan's work has not answered it; but of the six second-stage cases that formed his class last summer five showed marked improvement, three have gone back to work with the disease arrested, and one has died. His reports at two of the conferences included full reports of blood counts and blood pressure, and hemoglobin indices, as well as the ordinary sputum and urine and temperature and pulse and respiration records.

His other investigation related to blood pressure before, during and after hemorrhage in cases of pulmonary tuberculosis. His findings have been the surprising and important ones: (1) That hemorrhage from tuberculous lungs is never due to high blood pressure: but (2) that the bleeding consumptives have lower blood pressure than the average consumptive, and (3) that blood pressure for the hemorrhage case, just before the hemorrhage, is lower than the normal of that case; that (4) the blood pressure rises during the hemorrhage, and (5) that the blood pressure remains high for a

short time after the hemorrhage and then slowly falls to what it was before the hemorrhage. Dr. Dinnan is still working on this problem. His conclusions in this matter, considered in connection with Dr. Strobel's finding of a pathogenic pneumococcus in the sputum of all his bleeding consumptives, open up a wide field for speculation and study.

Because of my desire not to offend Dr. Dinnan's well-known modest disposition, and because I understand that most of you have seen the cases that composed the class in heliotherapy last year and are more or less familiar with his studies on the blood of the tuberculous, I will not dwell on his work at any greater length. That such work is important I need not tell you. I need not tell any doctor.

I will spend a little more time on the work done at the Shelton Sanatorium. You probably know less about the Shelton Sanatorium than about any in the State. I want to introduce you to it.

4. At the Shelton Sanatorium, Dr. Stockwell's best work has been on streptothricosis. A most difficult problem of sanatorium management is one that perhaps you would consider easy. It is none other than the problem of diagnosis. Has the patient tuberculosis? Of course, most of the patients that come to the State sanatoria have not only the physical signs of tuberculosis, but they also have easily demonstrable tubercle bacilli in their sputum; yet I think it is safe to say that in every tuberculosis sanatorium everywhere a varying percentage of the inmates have no tubercle bacilli in their sputum. They may have areas of consolidation or softening, or even cavitation in the lungs, and yet the most diligent search will fail to reveal a single tubercle basillus. Even guinea-pig inoculation may be negative. In these cases the various tuberculin tests may give unsatisfactory or contradictory evidence.

The State sanatoria are maintained for the benefit of residents of the State who have tuberculosis, and not for the benefit of persons who have not tuberculosis, even if they have suppurating cavities in their lungs. Nor are the sanatoria preventoria. A patient must have tuberculosis to be legally admissible. But when a patient with the physical signs of consumption has been sent to a sanatorium with a diagnosis of tuberculosis made by a physician of good repute, or by the staff of one of the best hospitals in the State, the sanatorium physician who takes it upon himself to pronounce that patient non-tuberculous must be very sure of his ground. The easy and ordinary way is to keep the patient and say nothing. Dr. Stockwell's way has been to study the patient and report his findings.

At the conference held at the Shelton Sanatorium he has already demonstrated twelve cases of streptothricosis, and in nine of the twelve cases there were no tubercle bacilli. All of these cases were severe progressive cases; they were all hemorrhage cases. The little granules of the fungus were shown at the conferences in the sputum of all twelve cases. The streptothrix was displayed in pure culture on glycerin and glycerin-agar. Under the microscope hanging drops of the live organism were shown, as well as many stained smears of the pure cultures, and of the streptothrical sputum. Then the twelve patients were exhibited and examined, and their treatment explained. Their treatment consisted in the administration of the iodides up to tolerance, usually 30 or 40 drops of the saturated solution three times a day. One patient received 70 grains three times a day. Remember, these were hemorrhage cases, and yet they received these heroic doses of the iodides. Now as to the results: Two died; one left without treatment; one remains unimproved; six have gone home without any symptoms left of their former serious lung trouble, and one has gone home improved but with some activity left in the lung lesion. One remains at the sanatorium slightly improved. And all of these cases were doing badly when Dr. Stockwell began his intensive study of them.

In order to persuade you that the subject is of importance to you as well as to us, let me relate briefly the history of one of these cases, the last one mentioned above, the one that remains at the sanatorium slightly improved. The patient, a husky man of middle age, had an attack of pleurisy in September, 1913. Several ribs were resected in November, 1913. A sinus persisted. In March, 1914, his left knee began to swell. At one of the best hospitals in the State various measures were adopted to cure the supposedly tuberculous knee; even a resection was tried. Nothing helped. Finally, in September, 1914, the leg was amputated above the knee. In January 1915, an abscess developed in the right hip. The surgeons in the hospital threw up their hands and notified the patient and his friends that the hospital could do no more for him, and that, as he had tuberculosis of the lungs and of the bones, the proper place for him was at one of the State tuberculosis sanatoria; therefore he was brought to the Shelton Sanatorium.

Routine examinations of sputum showed no tubercle bacilli in his sputum. After a while Dr. Stockwell's attention was directed to this fact. He immediately found the streptothrical granules, not only in the man's sputum, but also from the pus in the discharging sinuses in his hip and chest. The iodides have stopped the progress of the disease. The patient has gained in weight. The streptothrix cannot now be found in either sputum or pus. He has no more hemorrhages, but his bones are badly hurt; he has lost a leg. His future usefulness to himself or the community is very doubtful. It is distressing to observe his pathetic cheerfulness and to consider how different his circumstances would be to-day if any one of the many eminent physicians and surgeons who treated him during the last two years had known as much about streptothricosis as Dr. Stockwell knows now.

Here is another investigation pursued at this sanatorium and reported at a recent Shelton conference by the first assistant, Dr. Stilphen. It concerned the von Pirquet test. You all know the common judgment on the von Pirquet test: "It is of the greatest value in very young children, but it is of less and less value as the child grows older, and it is of no value in adults, because practically all adults have had tuberculosis at some time, and the positive reactions that practically all adults give to the von Pirquet test are of no assistance to us in determining whether the patient has now active tuberculosis."

Well, here is what they learned on that subject at Shelton, and how they learned it. They applied the test to all the patients in the sanatorium, one hundred and thirty-three in number. They applied the test to every patient at first with two kinds of Mulford's tuberculin, one made from human tubercle bacilli and one from bovine tubercle bacilli. They were so surprised with the results

that they wrote to Alexander for bovine and human tuberculin, and explained to Alexander that it was for a very important series of tests. They received special guarantees as to the quality of the tuberculin sent to them. They then went over all the patients again with the new bovine and new human tuberculin. And to their consternation the results with the second test were practically the same as with the first. Here are their results: Of the 133 patients tested, only 61 reacted. Of the 16 incipient cases tested, 10 were positive and 6 negative. Of these 10 positive incipient cases, 2 were positive only to human tuberculin, 2 only to bovine tuberculin, and 6 to both human and bovine.

Of the 55 moderately advanced cases tested, 26 were positive and 29 negative. Of these 26 positive moderately advanced cases 6 reacted only to human tuberculin, 5 only to bovine tuberculin, and 15 reacted to both bovine and human tuberculin.

Of the 58 advanced cases tested, 23 were positive and 35 negative. Of the 23 positive advanced cases, 3 reacted only to human tuberculin, 4 only to bovine tuberculin, and 16 to both human and bovine tuberculin. Of 4 cases of surgical tuberculosis tested, 2 were positive and 2 negative. Of the 2 positive cases of surgical tuberculosis, 1 reacted only to bovine.

It was only last December that Craig's article on the complement fixation test in tuberculosis appeared in the *American Journal of the Medical Sciences*. Those of you who have mastered the technique of the Wassermann test, and who have read Craig's article, will realize with what a love of work Dr. Stockwell and his assistants must be possessed when I tell you that at the conference held at Shelton last March Dr. Stockwell reported his findings in 31 cases, 26 tests and 5 controls. All his controls were negative, and 24 of his tests surely positive. His two negative tests were his first two experiments, and were probably negative because of poor antigen. Some of his tests gave a positive complement fixation test, although the patient had been negative to the von Pirquet test. This splendid result has been accomplished during the winter in spite of the fact that at the time of the appearance of Craig's article neither Dr. Stockwell nor his assistants had more than a reading acquaintance with complements, antigens or amboceptors. Isn't that interesting and important?

The medical staffs of all the sanatoria are studying the questions of the relation of typhoid to tuberculosis and some other fascinating problems that I am not at liberty to discuss to-night. At all of the sanatoria there is new interest in the patients and all that concerns tuberculosis. That is the cheerful verdict of doctors, nurses and patients.

In conclusion may I not fairly claim that Connecticut, as represented by those in charge of her State tuberculosis sanatoria, has begun a really serious and unusual and valuable study of the great problem of tuberculosis? If you consider the claim a fair one, I would ask you to show your sympathy with it by keeping in touch with us, by visiting the sanatoria, by giving us the benefits of any constructive criticisms that may occur to you as the results of your visits, by informing your people and your representatives in the Legislature of the importance to the present and future generations of Connecticut's dual role of Doctor and Student of Tuberculosis.

212 Orange Street.

COMPLEMENT-FIXATION IN PULMONARY TUBERCULOSIS.*

SOME CLINICAL OBSERVATIONS.

By ALFRED MEYER, M.D.,

NEW YORK.

Numerous reports have appeared during the last few years upon the value of complement-fixation in the diagnosis (or exclusion) of tuberculosis, especially the pulmonary form. The conclusions reached by various authors all seem to agree that there is *some* value in the test, both in confirming the existence of tuberculosis, either active or inactive, and in excluding it if the reaction is negative. There is, however, very considerable variation in the percentages of reliable results obtained in both positive and negative cases. This does not necessarily indicate the unreliability of the method, because it must be remembered that the different laboratory workers have employed different antigens, and for purpose of comparison the method used in all cases must be identical down to the minutest detail. At the same time, the widest publicity possible must be given to that method which seems to offer the highest percentage of reliable results so that the work may be repeated on the largest possible scale by many independent observers.

The object of this communication is (1) to give a short summary of work done on my cases this winter by Dr. H. R. Miller of New York with a new antigen; (2) to compare the results with similar work done by others, and (3) to illustrate the practical value by a few detailed clinical histories. The serological work was done by Dr. Miller at the Bacteriological Laboratory of the College of Physicians and Surgeons, Columbia University, New York City. Up to the present time he has examined the sera of a thousand cases obtained from many different sources. The material reported upon here was furnished by me from my service at the Bedford Sanitarium of the Montefiore Home, from my tuberculosis and general services at Mt. Sinai Hospital, and from cases in my private practice.

The method used by Dr. Miller was recently described by him as follows:

"The bacilli which so far have been used for the production of the antigen have been of the human type, some of them isolated by Miller, some of them obtained from Prof. Theobald Smith, some from the laboratory of Prof. William H. Park, and some from the laboratory of Parke, Davis & Co. They have been grown mainly on the gentian violet medium of Petroff, and on Miller's modification of this medium; also on Petroff's potato broth. It is at present the impression of the writer that the medium on which the bacilli are grown plays no great part in determining the usefulness of the antigen. It seems, however, to be important that a number of different strains should be used—that is, that the antigen should be polyvalent—and the use of relatively young cultures is advisable. So far, in most of the reactions, unheated bacteria have been used.† Inasmuch as the method of production, under these circumstances, is fraught with a not inconsiderable element of danger, we have recently begun to use bacteria heated to 60° for a half hour, and in the one series so carried out no

*Read at the Twelfth Annual Meeting of the National Association for the Study and Prevention of Tuberculosis, Washington, May 11, 1916.

†In a few of these cases the sputum was found positive only subsequent to the serological test.

*In a few of these cases the sputum was found positive only subsequent to the serological test.

deteriorating effect of the heating was apparent. These problems of detail, as well as many others, are being thoroughly investigated.

"Twenty mgm. of the moist tubercle-bacillus mass was weighed out, placed in a conical 15 c.c. centrifuge tube, and to it are added 90 mgm. of table salt. With a glass rod filed to roughness at the end, this paste is ground by hand for about one hour. Distilled water is then added to isotonicity; that is, 10 c.c. to the quantities above described. That is the antigen. Just before using, it is shaken up and the heavier particles are allowed to settle in the course of a few minutes. Except for the removal of these larger elements, the suspension is used as a whole without centrifugation and without filtration.

"The antigen so prepared has hardly ever been found anti-complementary in quantities as large as 1 c.c., and has given fixation with positive sera (the sera used in quantities of 0.1 c.c.) in amounts as low as 0.02 c.c. The titrations as well as the reactions have been done with one-half the original Wassermann quantities, using a sensitization of two units of amboceptor and two units of complement. So far we have used the anti-sheep rabbit hemolytic system. As a routine, the 37° one-hour water-bath incubation has been employed. A number of parallel series have been done by the four-hour ice-box method, but since this seems to make little difference in the results, the time-saving 37° method was decided upon as a routine procedure. The antigen appears to be quite stable. We have used with satisfaction antigens as old as six or seven weeks kept on ice."

Summary.—Of forty-eight cases with positive sputum, all but two reacted positively, equivalent to 96 per cent.* This result is even more favorable than appears on the surface, for one of the two exceptions (A. W.) had had negative sputum for seven months (eighteen examinations), had gained 33 lbs., and was in all probability an arrested case. The other exception (H. S.) was also in all probability an arrested case, having been afebrile for a year, and having gained nearly 18 lbs.

*This applies to all my cases.

It is necessary to go a little more into detail with regard to fifteen strongly suspect cases with negative sputum that reacted positively. The sputum in these cases had been examined from three to thirty times, some with antiformin.

The group of cases in Table I, not proven bacteriologically, represents a very common type for which clinicians are seeking additional reliable aid for a correct conclusion; and this need applies both to cases in which the interpretation of undoubted physical signs is uncertain, and to suspect cases without any physical signs at all, or is needed to corroborate exclusive skiagraphic findings, or to act as substitute for skiagraphic evidence if this is not available. Everyone of the above cases, with the exception of S. S., justified the positive complement-fixation test, either from the clinical or skiagraphic point of view, equivalent to 93 per cent. S. S. had a positive Wassermann, and although he had *x*-ray findings that might have justified including him among the proven tuberculosis cases, it was thought wise to exclude him for reasons which will appear later under my remarks on syphilis.

The case of G. F. is of especial interest because of the original *x*-ray diagnosis, the Von Pirquet findings and the change from two four-plusses to negative. It must be stated, however, that he had had a tuberculin injection of 0.005 with marked febrile reaction on Feb. 2, ten and twenty-two days respectively before his two positive complement-fixation reactions. As has been shown by Citron, tuberculin injections may cause the appearance of antibodies in the serum, which soon disappear. The subsequent course of this case, clinically and skiagraphically, indicated that his condition was one of chronic fibrosis with bronchiectases, and the suspicion is confirmed that the first and second positive complement-fixation reactions were due to the tuberculin injection, and that he had no active tuberculosis.

In two of the cases (M. A. and H. B.) a decrease in complement binding corresponded strikingly with clinical improvement. I leave it an open question whether there is any relationship between these two facts, and therefore of its prognostic significance. This can only be decided after the accumulation of a very large number of observations.

I wish to report also twenty-two cases of various diseases with negative reaction.

An analysis of Table II shows that in at least 15 cases out of the 22, equalling 68 per cent., the negative complement-fixation agreed with the clinical findings.

Of the remaining seven, M. J., L. K., F. P. and S. S. W., if ever tuberculous, were apparently healed cases; hence we may reasonably include them among the cases in which a negative complement-fixation reaction is reliable, which increases the percentage to 86. In three cases, however, M. K., J. R. and R. Z., the serological findings are not absolutely acceptable. M. K. and J. R. are sufficiently explained in the table.

The case R. Z. was a young girl of nineteen whose first hemoptysis had occured nine years before, after falling down stairs (traumatic tuberculosis, so-called?); again, hemoptyses four years before and two weeks before admission to my service at Mt. Sinai Hospital. According to her story, all these hemoptyses had been very large. While under my observation she had fresh hemorrhages on eight different days, as much as 11 ounces on one day, and totaling about 23 ounces, finally necessitating the induction of an artificial pneumothorax on the right side. The selection of the side for lung compression was somewhat difficult because there had been a complete absence of physical signs, with the exception of very slight crepitation on that side in the axillary region, and at that time radiography was not advisable because of the hemoptyses. From that date on, now five months ago, there has been no recurrence of bleeding, and she is much improved in general health; she has no cough, no expectoration, has gained a great deal in weight, and a guinea-pig inoculation with the blood proved negative, so I am still in a quandary as to the nature of her case.

In discussing tuberculosis complement-fixation in his recent work on "Pulmonary Tuberculosis," Fishberg says: "Most writers obtain positive reaction in patients with syphilis." On the other hand, Craig (*Am. Jr. Med. Sci.*, Dec., 1915) has reported that out of 150 syphilitics examined, only two cases gave positive tuberculosis complement-fixation, and in these two the symptoms of a coincident tuberculous infection were present. My own series shows two cases of syphilis, P. C. and S. W. (Table II), each with Wassermann four plus and each with negative tuberculosis complement-fixation. On the other hand, S. S. (Table I), a doubtful tuberculosis, admittedly luetic, had a positive complement-fixation, but also a positive Wassermann and *x*-ray findings that might be interpreted as confirmative of either or both of these diseases.

In a verbal communication, Dr. Miller tells me that he has examined fifty-four other cases with positive Wassermann and they were all negative for tuberculosis with his antigen, with the exception of one case, which was positive, and proved to be complicated by tuberculous peritonitis. This evidence strongly supports the view that with this antigen there is no confusion between the two tests, but that a positive tuberculosis complement-fixation in a luetic is simply proof of the coexistence of the two diseases.

The limited time at my disposal precluded my going extensively into the literature of the subject. Radcliffe (*Jour. Hygiene*, Cambridge, 1915, XV) had 89 per cent. positive results in 568 cases in all stages of pulmonary tuberculosis. In 11 cases other than tuberculous, mostly malignant growth, all were negative; in 20 suspect cases with negative sputa, 75 per cent. were positive; 45 apparently normal individuals, examined on 204 occasions, were invariably negative.

Craig (*loc. cit.*) found 96 per cent. of positive reactions in active tuberculosis and 66 per cent. in inactive. The test was negative in normal individuals, and also in patients suffering from other diseases.

Baldwin, of Saranac Lake, in a private communication, reports 56 per cent. positive in 32 suspicious cases and 90 per cent. positive in 10 known first stage; 25 per cent. positive in 32 healed cases, from four months to ten years. He also makes the remarkable statement that there were 30 per cent. positive in 20 supposedly healthy persons who had been long exposed to tuberculosis.

In conclusion, I would say that in my judgment the evidence offered by my cases, examined with Miller's antigen, compares most favorably with the results obtained elsewhere with other antigen; that it is in all probability no exaggeration to say that the method equals in value the Wassermann test for syphilis. It is most important that complement-

fixation tests, with Dr. Miller's antigen, be made on as large a scale as possible in sanatoria and, so far as practicable, in private life.

785 Madison Avenue.

SYPHILIS OF THE BLADDER.*

By JAMES PEDERSEN, M.D.,

NEW YORK.

The progressive pace set during the past twelve years by laboratory research workers, leading to precision in the diagnosis of syphilis in all its stages and to greater efficiency in its treatment, has been fully equalled only lately by the avidity with which practitioners have seized upon the thereby attained solution of many problems in medicine and surgery. An example of testimony to this fact is Dr. Barker's paper, presented at the New York Academy of Medicine's recent symposium on syphilis. It recalls to mind the keen clinician who, less than a generation ago, predicted that most ills of mankind could be traced to syphilis recently acquired or remotely inherited, and makes of him a seeming prophet, at that time without honor both within or without his own country. We are rapidly coming to *know* how much more general and occult is syphilis than was ever suspected.

The induction of Dr. Barker's paper, read on that occasion, contains an interesting chronological compilation of the research attainments and their dependent clinical facts. These attainments and facts are to-day so essential to precision in medicine and surgery that, closely summarized, it is permissible to repeat them here. Most of them fall within the past decade.

1. The discovery of *Treponema pallidum* as the cause of syphilis, followed later by success in growing the organism in pure culture.

2. The discovery that many animals are susceptible to syphilis, not only by transmission, but also by inoculation from pure culture.

3. The discovery of simple, easy methods of demonstrating the organism obtained from all sorts of syphilitic lesions, the chancre, the secondary eruptions, and gummata; the walls of aortic aneurysms, the brain in general paresis, and the cord in tabes; the organs in children dead of congenital syphilis, and the placentas of mothers of syphilitic children.

4. The discovery of the Wassermann reaction, applicable alike to the blood serum and the cerebrospinal fluid, and, through its clinical use, the proof that unsuspected syphilis is more widely spread than has been estimated; that the majority of cases supposedly well-treated before the Wassermann reaction control was known, still harbor infection; that many of the wives and children of supposedly cured luetics are infected, even though they show no symptoms; that the reason why a syphilitic child of a syphilitic father can be nursed by the mother without giving the disease to the mother (Colles' law) is that the mother is already infected (the child having been infected by placental transmission from the mother rather than by direct inheritance from the father); and that the reason why the apparently healthy child of luetic parents seems to be immune from infection, say, from an infected wet nurse (Profeta's law), lies in the fact that the child is already infected.

5. The advent of salvarsan, and by its use the proof that in many cases syphilis can be cured in reality and the Wassermann reaction be made negative permanently; that this cure is much more certain by intensive treatment in the early stages than by any form or measure of treatment late in the disease.

6. That the disease does not bequeath an immunity, and that reinfection can and does occur.

For the development of the infrequent topic this paper is to present, we have an extended thesis by Durœux (Paris, 1913), obviously covering all the cases recorded down to that date; certain references to works on cystoscopy; cases from the recent literature in this country; and five cases from my own observation.

From the Durœux thesis, it is apparent that syphilis of the bladder, as a lesion, either is rare or has been frequently overlooked or incorrectly diagnosticated. On the other hand, the thesis teaches us not to be surprised at the failure of the cystoscopists to identify the pathologic condition heretofore, for the reasons now to be described.

The forms under which secondary syphilis of the bladder appear are very similar to, often practically identical with, those non-specific and formerly commoner lesions—namely, simple hyperemia, simple ulcer, and papillary growths. To differentiate, the classical hyperemia of bladder syphilis is said to appear as discrete reddish spots, like macules, sometimes referred to a roseola of bladder; it may be symptomless. The characteristic ulcer is like the specific ulcer on any mucous membrane—more or less elevated on an area of edematous and injected mucous membrane, the edges definite, prominent, and firm, the base grayish with necrotic or hemorrhagic debris. They are usually multiple in clusters, rarely disseminated, and often grouped about or adjacent to one or both ureter mouths. When so situated, they may readily be mistaken for tubercular ulcers, especially if the appropriate symptoms of tuberculous cystitis be present—frequency of urination, more or less urgency, pain, tenesmus, and hematuria. The papillary growths of secondary syphilis have no features recognizable by cystoscopy that will differentiate them from the ordinary papillomata nor from the villous growth surmounting a malignant base.

The tertiary lesion of bladder syphilis—the gumma—is equally difficult of diagnosis by inspection. There is nothing about it to suggest syphilis. Whether ulcerated or not, it resembles either an infiltrating or a salient malignant growth.

By cystoscopy alone, therefore, the diagnosis of bladder syphilis—no matter what the stage—cannot be made. It must be supported by at least one of the corroborating essentials—the history, the Wassermann reaction, syphilitic signs elsewhere in the patient, the somewhat despised treatment test. Removing through the operating cystoscope a section of an ulcer margin or of a growth for the microscope, is no longer allowed by the best authorities. It is liable to promote dissemination and metastasis. The difficulties surrounding the cystoscopic diagnosis of bladder syphilis give that most available examination a regrettably negative value, in view of the fact and all our evidence would show that the incidence of bladder syphilis preponderates in the tertiary stage, when corroboration is least ascertainable.

Durœux's thesis points out this deficiency and displays the scepticism of the literature. He recites that Fournier, in 1899, ignored the subject in his first edition; that Guyon, as late as 1903, in

*Read before the Medical Association of the Greater City of New York, April 17, 1916.

his fourth edition, denied the existence of syphilis of the bladder; that in 1906 Nogues doubted all the alleged cases reported up to that time; and that Desnos and Minet, in 1909, did not accept syphilitic ulcer of the bladder. Kaposi is mentioned as alluding to rare but indisputable gummatous ulcers and cicatrices in the post-mortem bladder; while Caspar and other authorities on cystoscopic diagnosis are silent, non-committal, or unconvinced. The only French authors conceding syphilis of the bladder (though they refer to only rare tertiary lesions) are Legueu (Treatise on Urology, 1910), and Hallapeau and Fouquet (Treatise on Syphilis, 1911). Proksch, in his great bibliography, accepts as clearly authentic only some of the occasional post-mortem ulcerations of the bladder, reported as specific.

A glimpse into still earlier history is interesting. According to Durœux, the earliest mention of bladder syphilis was made by Morgagni in 1767, in the form of a specimen corroborated by lesions in the glans, epiglottis, and tongue. The next record is a specimen presented by Follin in 1849. Ricord, in 1851, described in great detail and illustrated two cases, proven later by autopsy. Close upon him follow Virchow and Vigal de Cassis. Beginning with 1899, the observers and cases begin to count up, though very slowly. Matzenauer (1900) seems to be the first who used cystoscopy in these cases.

Of the twenty-six tertiary cases thus brought together by Durœux, the incidence of the chief features was as follows (expressed in percentage):

	Cystitis		50
	Hematuria		35
	Lesions elsewhere		62
	History	positive	54
		negative	8
Of the lesions in the bladder	Papillomata		16
	Ulcer	single	16
		multiple	23
	Gummata		27
	Undefined		4
	Wassermann reaction (positive)		8

Of the fourteen secondary cases collected by him, two are incompletely reported post-mortem cases (Fenwick, 1; Neumann, 1) and one is the case of a four year old child who died of syphilis contracted from a wet nurse. The lesions were chancre of the mouth, a skin eruption, and ulcers of the pharynx, urethra and bladder.

Three cases by Pereschiwkin and five by Frank (1909) seem to have been put on record to negative the claim made by Nitze in 1907 that there existed no cystoscopic picture of a syphilitic bladder. The eight cases of these two observers seem not to have been reported in detail. Asch's one case (1911) had developed sharp cystitis eighteen months after a vulvar "abscess," with adenopathy, and twelve months after a gonococcus infection. Multiple bladder ulcers were found. One other case gave a positive history and had a bladder ulcer.

Counting the case of the four year old child, the only other satisfactory report in this group of fourteen cases is that made by Durœux with Levy-Bing (1912). Making cystoscopy a part of the routine examination of 100 luetics, they discovered ten small vesical ulcers in a patient without symptoms of cystitis, but having confirmatory syphilitic signs and a positive Wassermann.

Examining recent works, we find the French well in the lead with both plates and text, practically all based on the cases collected by Durœux.

The Germans are a close second, through Frank of Berlin, who exhibited a series of illustrations from two cases at the German Neurological Congress in 1909.

The English come third, with Thomson-Walker's good description of syphilis of the bladder, though he quotes only Asch, apparently not knowing of the French thesis.

Our country follows in a minor fourth place; our recent books either make no mention of the subject or allude to it only casually. In our journals, where we make a better showing, the following cases are found:

The one reported by Rush (Mobile), in 1913, is interestingly suggestive. The patient, 66 years old, had contracted syphilis when 24, and it had been thoroughly treated. He had had symptoms of cystitis for many years and presented a notably enlarged prostate. The case had been variously diagnosticated as Bright's disease, carcinoma of the rectum involving the prostate, senile enlargement of the prostate, and vesicle calculus. The existing nephritis was held to bar prostatectomy. Owing to hemorrhage, cystoscopy was impossible. Wassermann reaction, weakly positive. After the second intravenous salvarsan, all his symptoms began to improve and the Wassermann became negative. Then twenty-six injections of salvarsan were given, resulting in an almost total disappearance of the symptoms and a marked reduction in the prostate. The fact that the cystitis had long antedated the prostatic obstruction, appears as ground for the inference that a gumma of the prostate and bladder was the pathologic condition.

Simons (1913) reported a twenty-four year old man who, denying syphilis, presented vesical symptoms suggestive of tuberculosis. Cystoscopy showed clean cut ulcers posterior to the trigone. Local treatment aggravated the symptoms. The Noguchi test was then found positive, and intramuscular injections of mercury promptly affected a cure. Eventually the blood became negative and the bladder normal.

Buerger, the same year, described two cases of ulcer of the bladder; Simons later commented that the second case may have been syphilitic, as the ulcer healed under mercurial treatment, although the Wassermann was negative.

Hunner (Baltimore, 1915) enumerated eight cases of chronic ulcers of the bladder, neither tuberculous nor malignant. Five were treated by excision. The other three did not improve under non-operative treatment. He does not seem to have suspected syphilis, and Cones calls attention to the fact that syphilis was not excluded.

Finally, Schapira (1915) described a case of probable re-infection, the first infection occurring in 1907, the second in 1912. In 1914, within four or five months after five injections of salvarsan, when the Wassermann was negative, bladder symptoms developed. The cystoscope showed a congested trigone, two ulcers recognized as syphilitic, and a gumma. Another administration of salvarsan acted as a provocative; the Wassermann became strongly positive. Under continued treatment, complete recovery occurred.

The cases from my own experience are as follows:

Case I.—A married man, 71 years old, in moderately good general condition, with two apparently healthy children, aged 13 and 11 years respectively. (The patient did not marry until his 56th year.) Undoubted syphilis in his 21st year. Mouth medication for only one mouth. Ten years thereafter, he began to have so-called "liver attacks." These seem to have recurred frequently, with increasing severity, finally

culminating in a grave condition in 1905. He was seen by a gastroenterologist, who soon changed his tentative diagnosis of carcinoma to syphilis of the liver. Six weeks of intensive treatment effected a cure.

At this time (1905) there appeared the first bladder symptoms usual to any 66 year old man—painless frequency of urination. Later on, hematuria was added. Two trifling attacks in the course of the intervening five years were followed by sudden, almost profuse, hematuria, with clots sufficient to cause intermittent retention. He had been obliged to use a catheter off and on for a week before he was referred for treatment.

The clots and rapid oozing made cystoscopy difficult; but a growth (taken to be a probable malignant neoplasm) was made out, apparently involving a large area of the bladder base and the lateral walls to a small extent. Cystoscopy was protested until after antisyphilitic treatment had been tried. This was carried out in the hospital and forced. Though favored by rest in bed, the bleeding only slowly abated; but by the end of the month a clear view of the bladder lesion was had and the patient could go about almost at will without greatly increasing the then minimal oozing.

The lesion is correctly described as a "fleshy" or compact growth, with a few moderately villous formations and an unusual amount of necrosis. By continuous sloughing, the growth gradually decreased in size until, nine months later, only a small mass with a narrow villous margin was left near the right ureter mouth. Posterior to the trigone, one area, originally hidden if not involved, now presented a reddish-brown, finely striated appearance, such as might be formed by a recent scar in the mucous membrane of a partially distended bladder.

It is admitted that the course of this case during the second half of the two years and nine months the patient was under observation, creates the suspicion of an underlying or resultant true neoplasm, as opposed to an unconditioned gumma; the necrosis ceased, nevertheless the tumor did not disappear wholly, and the tendency to hemorrhage after over-exertion was ever present, though slight. Occasionally considerable bleeding occurred. To offset the suspicion, however, is the fact that constant treatment was not possible, owing to the patient's distance from the city and other contingencies. He died in December, 1912, of an extensive erysipelas.

An interesting and not wholly irrelevant query would be whether this patient's practically neglected syphilis, contracted when he was twenty-one, was still communicable at fifty-six when he married, and whether it had anything to do with a chronic joint trouble for which his wife was under the care of an orthopedic surgeon. To further complicate the matter, is his history of several attacks of urethritis, prior to marriage.

Case II.—March 11, 1915. A man, aged 34, married, came to the Post-Graduate Clinic, complaining of hematuria, apparently the result of traumatism. He had been accustomed to pass a more or less flexible bougie at intervals, to dilate urethral strictures that dated from boyhood. Their cause could not be ascertained. Cystoscopy showed thickening and diffuse congestion of the mucous membrane (the usual picture of a long-standing, chronic cystitis), and, in addition, a marked but flattened infiltration of the right anterior wall, with an open lesion posteriorly, supposed at that time to be the wound made by the patient's bougie. The infiltration was so marked and circumscribed that malignancy was suspected.

The patient now called attention to a reddened, semi-fluctuating swelling, occupying the right supra-spinous fossa. When cut down upon, it proved to be neither an abscess nor an infected lipoma, but a full-fledged gumma, in spite of a negative history and a negative Wassermann. The fossa was cleaned out and drained. Under intramuscular injections, it healed well, though not without further necrosis and suppuration. Within four weeks after treatment was begun, cystoscopy showed a general improvement in the bladder.

The patient so appreciated his improvement that he disappeared, only to report again at the end of nine months that hematuria had returned. Cystoscopy (about four weeks ago) revealed much less chronic "cystitis," the first infiltration about half the original size, a peculiar tesselated appearance of the membranous urethra posterior to the trigone—due apparently to the contraction of superficial scars—but no discoverable ulcer to account for the hematuria. The man is again under antisyphilitic treatment.

Case III.—June 23, 1915. A robust looking woman, 44 years of age, married. Her only child, now 25 years old, developed an eruption soon after birth that was diagnosticated congenital syphilis. He was treated successfully.

Apparently this patient, the mother, had good, if not perfect health, throughout and down to her thirty-seventh year, when frequent and painful urination developed. Hematuria, with clots, supervened. The bladder was variously treated by many physicians the world over; repeated cystoscopic examinations disclosed "ulcers." Finally, in January, 1915, while in Paris, the diagnosis was made. Intramuscular injections every two days resulted favorably at once, and she continued in fair comfort for nearly five months, though the treatment had not been concluded.

When she came under our observation, she was again urinating every fifteen minutes during the day and every half hour at night. The urine was turbid and slightly blood-stained. Gross hematuria had not occurred since the treatment in Paris. Cystoscopy, with only two ounces of fluid in the bladder (its maximum capacity at that time), (no anesthesia) revealed an almost general thickening of the mucous membrane, with here and there areas of sharply defined congestion set with ulcers to which mucus-like pellicles were more or less adherent. From approximately the left ureter mouth, a narrow ridge—its free edge marked by a linear ulcer—curved upward across the vault of the bladder, gradually narrowing, and vanished into the wall at the corresponding landmark on the right side. The ridge would probably have been less salient had full distention of the bladder been possible. No bleeding point was seen, nor did the urethra bleed, though it was very sensitive. Under intramuscular injections, she improved rapidly. My notes state that within ten days she was retaining her urine three hours. The unfortunate woman had suffered so long and patiently that, as she demurred, I did not insist upon a control cystoscopy when she was about to leave the city.

Though the following case is chargeable with a positive history and positive Wassermann reaction, the bladder factors therein were so minor and ceased so promptly under the intensive treatment given that only a summary will be necessary.

Case IV.—A 62 year old man, with a prostate surprisingly small and soft for his age, and with only a drachm of *clear* residual urine, complained of frequency and an urgency so great that he was liable to incontinence during sleep. He could not always wake up promptly enough to control the urinary impulse. Under antisyphilitic treatment alone, improvement set in at once and progressed. His day intervals now are normal; during the night he urinates but once. The assumption is that his lesion was a specific hyperemia of the bladder. His rapid improvement precluded the necessity for a confirmatory cystoscopy.

Case V.—November 16, 1911. A married woman, 30 years of age. Never pregnant. Two gonococcus infections by her husband; the first when twenty, the second when twenty-six. Apparently the distressing frequency and pain of urination date from the first urethritis. She has never been free from these bladder symptoms since. Undoubtedly, they are aggravated by the colon bacillus infection present. Cystoscopy, negative. Urethra deeply congested. Eight months later, however, an ulcer and punctate spots were discovered in the bladder.

Intermittent treatment based on those diagnoses and continued over a long period gave considerable relief at times, but only temporarily. Two urinations at night and a three-hour interval during the day was the best result obtained. In addition to local measures, the treatment included two courses of colon bacillus vaccine (autogenous and stock), and finally removal of the infected (right) kidney (May 22, 1913). At this time there was stricture of the right ureter and an ulcer at its mouth. The first pelvic examination, made early in the course, excluded any abnormality, but the second disclosed a marked retroversion. This is said

to have been corrected by her physician. No benefit resulted.

Last November, after she had been absent for nearly eighteen months, the Wassermann was found ++; the Schwartze, negative. Her family physician is carrying out the antisyphilitic treatment. Both he and the patient report that she has less pain and frequency, as a rule. She now urinates only once during the night.

Though the last two cases may not be accepted as conculsive, they nevertheless present a reasonable, if not a strong, probability, on the basis of which they are believed to have a place under the title of this paper. In any event, Case IV serves to point out that bladder hyperemia may be related to syphilis in the same way that it is to several other conditions; and Case V helps fix the fact of occult syphilis as a contributing cause in some highly complex cases.

The conclusions to be deduced are these:

1. Syphilis of the bladder is an entity often overlooked or not recognized.

2. It may manifest itself in one or more of several possible pathologic lesions, only one of which—the punctate hyperemia in multiple spots, the so-called "macule"—is pathognomonic.

3. The other lesions, having the same general appearances of benign or non-malignant lesions not due to syphilis, cannot be differentiated cystoscopically; some corroboration is necessary to the diagnosis.

4. Suspected, recognized and treated, the prognosis seems uniformly good.

10 East Forty-first Street.

DRUG ADDICTS AND THEIR TREATMENT.

By T. D. CROTHERS, M.D.,

HARTFORD, CONN.

Within the last few months a number of very elaborate papers have appeared concerning drug taking and the methods of treatment. These papers indicate an increasing interest, and show that the profession has at last awakened to the responsibility of being better able to treat and counsel such cases than the empirics who have largely occupied this field.

In July, 1915, there were forty-one homes, sanatoriums and institutions for the treatment of drug addicts. A very large number of them were obviously empirical, from the fact that they advertised new and secret drugs. They claimed to have discovered some process, unknown to the regular profession. Four of these concerns used remedies that had been found in foreign countries, and they evidently had the monopoly of the importation of these drugs. Others claimed not only the discovery of new drugs, but combinations of drugs, never made before, and new methods of using them that would produce most unusual effects.

Evidently a great many persons are treated in these various institutions from the fact of their number and variety. The profession recognizes this very clearly by the increasing number of victims coming for help who have tried these various advertised cures and relapsed, and their condition is more serious than ever before. Hence the profession is greatly concerned to know what to do, and how to treat these poor victims, who are in a large proportion of cases members of good families and among the patrons who are quite able to pay for medical attention. In consequence of this, during the last few months a number of papers have appeared from writers who supposed they had attained a degree of certainty in their methods of treatment. An outline of what may be termed the general principles which are to be followed in the care and treatment of these addicts will give a little wider view of the problem that is becoming more urgent every day.

Hospital treatment is found in most cases to be the first essential. The patient must leave his surroundings and home life and go where all these conditions can be directed and controlled. The first object is to remove the drug, and this can best be done in exact surroundings and conditions of living. The after-treatment may be conducted at home, under the care of the family physician, but at first the patient is far too weak and neurasthenic to be able to take care of himself in any particular way. In the hospital the physician will determine what plans to follow, whether the withdrawal of the drug will be rapid or slow, and how far the patient will cooperate in the treatment. In some instances a rapid withdrawal is called for. In others a long, slow removal gives a chance for building up the mental and physical conditions of the patient. The theory that shock will follow from the rapid removal is not sustained; no matter what quantity the patient may be taking it can be reduced greatly without the patient being conscious of it. Below that many symptoms will develop, mostly of a mental character, that require treatment. Experience shows that substitutes of the narcotic family are not only dangerous, but oftentimes worse than the original.

The claims of irregulars that the original drug has been removed and they are cured, and the fact that preparations of belladonna, hyoscyamus, and other drugs are being substituted, are absurd and misleading. The removal of the substitutes provokes the return to the original drug, or something equivalent to it. The various theories of shock, depression, and functional disorders are largely mental, and are overcome by natural methods and the recuperative powers of nature.

The condition of the morphine addict is an assemblage of toxemias and autointoxications, obsessions, delusions, and various forms of functional and transient paralysis. These are most readily removed by eliminative measures through the bowels and skin, together with hydropathic appliances of every description.

Fatigue, weariness, and morbid consciousness or absence of consciousness of his real condition are always present. The arterial tension is extremely variable, rising and falling alternately from conditions unknown, associated with unstable heart's action and extreme susceptibility to a great variety of conditions that seem to be governed by surroundings. Irritation of every description is registered by the tension. Drugs and spirits or anything that will relieve this irritation is most grateful, and sought for. Tobacco, coffee, tea, and tinctures, patent drugs or anything containing alcohol seem to be very suitable for the occasion, and yet all are dangerous and complicate the real condition.

The short cures in which excessive purgation, bathing, rubbing, and drinking large quantities of water give very pronounced hints of the actual requirements. The supposed shock from withdrawal does not appear, and the patient is buoyed up with hope that the drug will never be resumed again, because there is no possible desire for it. This is accomplished by the sudden overwhelming appeal

to the organism, which is certain to be followed by reaction.

The week or two weeks' treatment in which the patient is put to sleep by another drug, on the supposition that the substitute can be dropped and the original craving will be gone, depends on so many unknown conditions as to be practically unreliable. The mental state of the patient, who on awaking from the chemical stupor realizes that he has escaped the former drug, becomes a literal obsession that overcomes a great variety of symptoms for a time, but sooner or later there is reaction, and the hope of permanent recovery goes down in relapse. He has nothing permanent on which to build, except the fleeting suggestion of cure, which the organism is unable to sustain.

The fatigue, pains, and aches which are overcome by morphine must be treated, as also the conditions of the brain and organism that call for relief and appeal for help. The withdrawal of the drug which gives this help is only a small part of the treatment. The very unusual histories of cases reported give the best evidence of this. Thus in one instance a morphine addict went to the mountains, under the care of a physician, and drank immense quantities of water every day. He lived on a grain diet, took a hot bath every morning, and lived practically out of doors. The doctor, who had great faith in medicines, gave at short intervals a solution of skull-cap. In a short time the patient gave up the morphine voluntarily, and in a few weeks was discharged cured. The doctor attributed the cure to this particular drug. In another instance a chronic addict was put on a spare diet of grains; he walked four times a day a mile or more to drink large quantities of mild mineral water. He recovered and the mineral water was given credit for the cure. A third instance reported was of a woman who had been addicted to morphine two years. She lived a life of great ease, without any purpose or object. Suddenly she was called to Colorado to take charge of her brother who was dying from consumption. She went up to a mountain shack and was forced to do a great deal of nursing, preparing of foods, carrying of water, and other duties that she had never done before. She gradually gave up the use of the drug and substituted hypophosphites which her brother was using, and in this way she remained for nearly a year, actively engaged in this mountain cottage, and returned entirely restored. The doctor reported the case as one restored from hypophosphites. These three are examples, of the removal of causes which were unknown at the time, but really were the largest contributors to the continuance of the drug addiction.

Whenever the states of irritation, exhaustion, and depression are removed, the desire for the drug dies out. This gives a most significant hint of what the cure of drug addictions really means. Treating symptoms complicates the case, and is far from being scientific. Elaborate details of what means or measures remove the discomfort and psychical symptoms, which follow when the drug is taken away, of themselves are of very little value.

The theory that opium produces a toxin which circulating through the blood increases the demand for it, and that of the products of acids that intensify the present conditions, sound very learned, but somehow they do not go back to the original causes. A great many cases have been reported where the removal of some sharp irritating cause, such as a spicula of bone pressing on a nerve, a neuralemma from a contused nerve, a depressed bone of the skull, a tapeworm, or a great variety of active sources of irritation, has been followed by the giving up of opium in any of its forms.

It is not uncommon in the general practice of physicians to find persons who are taking opium or its alkaloids secretly, with or without any particular cause. The ordinary physician is satisfied with the patient's statement, as to why he began the drug, and beyond this there is a range of moral causes which the physician acquiesces in. It would seem absurd to concentrate all efforts on the removal of the drug and neglect the causes. It is simplicity itself for one to go here and there for two or three weeks and have the drug removed by substitute methods of all sorts and kinds, and then come out buoyed up with the faith that he has escaped and will never more relapse.

The family physician who has charge of these cases soon discovers a great variety of complicating symptoms which did not appear before. The patient apparently is free from the drug, but other symptoms break out of a more aggravating character—insomnia, periods of restlessness, of excitement, or unusual elation or depression.

If he is in business circles he will complain of exhaustion that is most unusual and does not yield to the ordinary remedies. He will have symptoms of so-called rheumatism, muscular stiffness, neuritic pains, and his digestion will be impaired. His eyesight will be weakened and a great variety of other general and local symptoms will appear. The original causes have not been touched. In addition, there have been drug complications and drug injuries which are more or less traceable. Thus the person treated with hyoscine and belladonna compounds will develop a class of symptoms that seem to have some connection with these drugs. The delirium and delusion from hyoscine leave some vestige and conditions that linger long after the drug has been taken. The defective eyesight that calls for readjustment of glasses, where belladonna has been given freely in the treatment, suggests drug injury. In cases where bromides have been given for a long period, there are degrees of dullness and loss of energy that give the same intimation. All these are hints that the condition treated in the withdrawal stage by narcotic drugs is full of peril and possible future disturbances.

When the physician discovers the use of morphine in his patient a very active study should be made to find the original cause and the contributing conditions. A reckless physician may give morphine to a toxemic case for some little time as the most simple way of removing the symptoms. Later the patient continues the drug. The fact that the morphine was given for toxic conditions, and that it produces a toxic state, outlines the treatment clearly.

In the nerve-exhausted, care-distracted men and women, who find relief in morphine, another set of suggestive causes indicate the methods of treatment. There is often a common-sense viewpoint which is not recognized; most of the modern writers give great emphasis to the withdrawal of the drug and consider the after-treatment a matter of small moment.

The psychical treatment, which considers the effects of mind on the body and the influence of surroundings and occupations, opens the widest road for practical results. The frequent relapse of such

persons with the loss of faith in the patient and of confidence in the physician in his permanent restoration, all come from the absence of exact psychical and physical study and treatment.

The drug-taker is always aged physically, and is subject to a great variety of conditions, which can be removed as positively as any other disorder. He may have inherited defects, and he certainly has acquired some of them, but with proper means and study, they can be overcome, and to a large extent removed.

I have found in my long experience that a form of re-education and mental change, or to use a larger term, reclamation, which signifies a complete change in mind and body and a new consciousness of how to live. I have noted many persons who were cured, in the sense of never using the drug again and living many years a useful life. I have seen instances where it would seem that the drug addiction was self-limited and after a time would die out in ordinary favorable conditions. Its very intimate association with alcohol of course complicates and increases the degeneration, but even here, there is not unfrequently seen a recuperative power that is startling.

The so-called incurable cases are in persons who use any sort of drugs or spirits that have narcotic effects, going from one to another as circumstances demand, but even these persons are curable by ways and means that seem astonishing at present.

One such person is recorded in medical literature as having made a permanent recovery from the use of alcohol, a second recovery from opium, a third from chloral, and a fourth from cocaine. The physicians who treated this man, spoke very positively of the effects of certain drugs or combinations of drugs and believed their means and methods to be responsible for the cure. In all probability each one of these physicians was not aware of the patient's cures in other institutions. He was a man of some property and prominence and moved about from place to place and was secretive to the last degree. After the last cure, he was killed in an accident, or he might have furnished other details for the literature on this subject. Experience brings out one fact as basic of all others. The patient should go under the care of a scientific physician; scientific in the sense of being careful, conscientious, and exact in his work and a student in the sense of studying each case by itself, and not according to the theories or traditions of others.

The patient should be made to understand that the removal of the drug is by no means the whole treatment, that there are other very serious derangements that must be found and corrected, and that his full cooperation is required covering a long period of time. He must recognize that the use of morphine is only a blundering effort to cover up his real condition. He resembles the ostrich who in times of danger buries his head in the sand.

The continuous use of morphine not only covers up the pain signals but creates other centers of distress and so adds to the degeneration and decay, or rather aging of the patient to an extent beyond any possible conception. The patient's viewpoint is a very dangerous one and in many instances it is practically an insane one, meaning by this a perversion and reversion of natural reasoning and thought, and an absence of correct judgment of cause and effect. Many of the morphine addicts show a degree of mental vigor in other respects, but concerning themselves and the use of the drug they are practically dements, full of delusions and illusions, and are utterly unable to judge correctly of what should be done. The more intellectual the patient, the more dangerous and subtle the delusions are.

When the patient realizes this thoroughly and puts himself implicitly under the care of a wise physician, the beginning of a permanent cure is made. The physician should then have no difficulty in studying the case and determining the causes and exact conditions present; then applying the best means and methods for their removal. All this is along the line of every day practice and training. There are no specifics or mysterious drugs with unknown effects and nothing in the nature of a miracle here. The patient's conception of what he wants is one thing, which is very likely to differ widely from that of the physician, but through it all, there must be a degree of confidence and positive deference to medical judgment and skill.

Details of how this can be done and the exact means to be used can only be stated in the most general terms, because no two cases are alike. The presence of toxemias and autointoxications is universal to all cases, and therefore suggests the first question of treatment; then follow all degrees of physical and psychical palsies which require their special distinctive treatment.

Eliminative measures, which include appeals to the skin, bowels, and kidneys through baths, cathartics, massage, and various other measures depending on the history and habits of the patient, are necessary. Baths in mineral water seem to supply a most practical demand. Of these the soda, salt and gas baths are the best. Where the skin is very inactive a mineral bath in hot water is useful. Where the skin has been very active and perspiration marked, salt baths and acid baths are excellent. The hydropathic measures must be determined from the previous habits of the patient, his occupation and diet, in the same way that cathartics given should be studied and adapted to the person. The next question is that of nutrition and sleep. The previous history and present conditions will usually furnish the best hints of what measures are practical. Then occupation, exercise, and regular habits of living are to be treated in the same exact way.

Psychically the patient's consideration of his own condition and his reasoning as to what he needs and what is lacking often give most important clues for restorative measures. The study of the patient's mentality is as important as his physical condition. If he has lost faith and courage and becomes pessimistic where he was the opposite before, this is a physical hint of importance. If he has suffered from injuries, shocks, and mental changes that profoundly influenced his nervous system, they are distinct conditions to be overcome. The chronic addict always exhibits mental lowering and defects of ordinary reasoning that are of course incident to the continuous anesthesia of the drug. These are questions for study, quite as important as the exact dosage necessary to keep him comfortable.

Stretching out from this point there is a great unknown field of symptoms, dating from distinct causes which should be understood and treated with as much exactness as the pain symptoms for which the drug is taken. As to what drugs may be given or depended upon for relief, there can be no absolute certainty of uniform effects. There are many drugs called tonics and alteratives that serve a good purpose, and there are many mild narcotics of

the vegetable class that are extremely useful and in some instances have a decided value, but all this must depend on the condition of the patient and the good judgment of the physician.

There is always a degree of complexity in the symptoms and a certain sudden shifting of mental and functional activities of the patient that require the highest kind of skill to meet and overcome. The attempt to do this by drugs alone is crude and usually a failure. It should be understood that the effects of long addiction to narcotic drugs have very seriously impaired the adjusting centers of the brain and its capacity to accommodate itself normally to the exigencies of the present, hence there is a degree of degeneration and impairment that must be recognized and provided for.

While the removal of the drug is the important part of the treatment it often uncovers a great variety of symptoms which are really worse than slavery to the narcotic. The specialist can treat the former most practically, but he rarely has the opportunity to carry on the after-treatment other than by advice and counsel, and in this the family physician has a larger field for the exercise of his best skill and judgment.

The central fact should never be forgotten that drug addictions are distinct neuroses and psychoses, amenable to treatment and curable to an unknown extent. Preventive measures here are pronounced and physicians recognize susceptiblities and often exercise judgment in preventing the development of these nueroses by discretion in the use of opium.

When the addiction is fairly formed the complexity of the symptoms and general control of the case present so many obstacles in the treatment that physicians hesitate, and not unfrequently permit such cases to fall into the hands of irregulars. Later when they relapse and come back for active treatment, the difficulties increase and in the absence of text-books and authorities telling exactly what to do, there is more or less confusion. All this reflects on the training of the physician and the disposition to accept theories and traditions from unknown sources and to neglect the same exact scientific study and treatment of such cases as are given in other departments of medicine.

Another fact should be emphasized. Physicians should discourage patients from expecting help from irregular and mysterious sources and depending on specifics and specific treatment. Here as in every other department of medicine, it is cause and effect and a study of the exact laws and conditions which control the growth, development, and termination of narcotic addictions.

Medical colleges should make the study of these neuroses a part of their training. Post-graduate schools would find instruction in this department welcomed by an increasing number of physicians. It is obvious that the treatment of drug and spirit addicts, now largely in the hands of quacks, must be brought into the range of scientific studies, the demand for which is apparent in every section of the country.

Treatment of Syphilis at the Providence City Hospital.—H. P. B. Jordan states that 606 and 914 have practically the same therapeutic value and that too much reliance is put upon these drugs by the laity. All patients should receive mercury treatment after 606 treatment as efficiently as they did before the introduction of the latter, and in latent and tertiary cases a good course of mercury should be given before salvarsan.—*Providence Medical Journal.*

PAINLESS AND SHOCKLESS CHILDBIRTH.

TWILIGHT SLEEP.

By M. W. KAPP, M.D.,

SAN JOSÉ, CAL.

In the Medical Record for November 14, 1914, I gave a short report of my success with a new method of modifying the pains of parturition. I beg space for a more extended report after another year of experience with the method.

Fear is one of the greatest inhibitors of normal functioning. Fear retards mental, physical, and spiritual development. How can a mother develop mentally and physically and give the correct development to a child in utero when her mind is filled with thought of fear of the distress of the pregnant state and the agony of the accouching chamber. For ages, from the depths of their agony have parturient mothers said, "For God's sake, doctor, do something to relieve me." We can now answer that appeal.

Very recently, within a few days of each other, I had three primiparous cases and in each one, before I left the house after the confinement, the woman planned for the next baby as coolly as if the having of babies was a mere joyful occasion. I considered that the best compliment for my method that I could have.

When we can make womankind *know* that the pains of parturition can be made bearable and even easy then we shall be laying the foundation of a new consciousness where fear does not enter and motherhood will be glorified anew. I used to dread my confinement cases, but do not dread them now, for I feel master of the conditions. When an expectant mother comes to me now and engages me for her confinement I can assure her that her pains will be bearable and that she will receive her baby in her arms joyously. The very fact that I can tell her truthfully that she will not have the severe pains lulls her fears and puts her in a better attitude to take the pains.

I have seen many a woman enter the pangs of labor with dread and fear and when I proved to her that the pains could be and were modified so the agony was eliminated then she would bless me and put forth her best effort and assist gladly in the expulsion of the child.

Probably the first case where I used my present method will illustrate what I have had told me dozens of times. I was confining a quadripara. I had confined her twice before and she was no shirker and her pains were very hard at each confinement. As the head was entering the upper brim of the pelvis she would be almost in a frenzy with each pain. She would not bear down. She begged piteously for me to do something to relieve her. It was too early to give her chloroform and besides I did not like to give her chloroform as she had a history of very severe hemorrhage at each confinement. I was almost desperate for I knew her so well that I knew her pains were all that she said they were. Why I gave her what I did I do not know only that there was some vague impulse for me to try it. I gave her hypodermically 1/12 gram heroin hydrochloride. In about fifteen minutes she turned to me and said, "Now I can bear down. My! what a relief." She then took hold of the straps and the way she could bear down and the manner that she hustled that child into the outer world was a revelation to me. And this time there

was no hemmorrhage though that may have been due to the fact that for a week previously to the confinement I had given her ten drops of adrenalin chloride twice a day.

After the baby was born the mother turned to me and said, "Doctor, give that hypodermic to every woman having a baby. It's the greatest blessing that I have ever known."

The above case occurred in August, 1911. I used the drug in practically all my cases for three years when I went to New York City for post graduate work and to study the Freiburg method of "twilight sleep." I at once saw the uselessness of that method for the general practitioner, though a study of it has helped me to modify and perfect my methods of procedure.

In my opinion amnesia is not the most desired object to be attained in confinement. Analgesia is the desideratum. With drugs that produce amnesia the patient does not use her voluntary forces to assist in the expulsion of the child. With a condition of analgesia the patient can employ all the forces that nature has given her to hasten the progress. A mother has all the joy of knowing when her child is born. And it is a joy when the pains have not outweighed all else.

My method is a practical one adapted to use in the humblest home as well as in the most elaborately furnished home or hospital. Heroin intelligently used is the best aid yet found for general use. Heroin does not bring babies without the help of the mother and the doctor. Heroin is a blessing if used with brains. Some people seem to think, when you offer them an aid in parturition, that it will be something vague or mysterious that relieves the mother of all effort or responsibility. I explain to the prospective mother that the laws of nature demand that the child be born through the efforts of her voluntary and involuntary forces. I aim to help her use her natural forces by using a simple analgesic that does not destroy the involuntary forces and by its mild anodyne effect allow her to increase her voluntary effort and thus make labor less in length of time and *very much less* as to suffering and pain.

When I am called to a case in labor and the woman is a multipara, I satisfy myself that the pains are real labor pains and strong enough, I give a heroin at once as labor is usually short and the mother has known from previous experiences what the real pains are. In a primipara I always wait until the pains become severe enough that the prospective mother may know what real pains are like. I do not care what stage of labor the patient is in—the pain is my guide for the giving of the heroin.

I then wait for the effect and while doing so attend to the asepsis and preparation of the patient if that has not been attended to before. I watch to see if the effectiveness of the pains lessened or changed in any way. In from 10 to 20 minutes the patient often complains of a dizziness or a slight feeling of intoxication, and almost always a sleepy feeling. Right there is one of the most important moments of your work. Explain in a very firm manner that now the hurting pains will be lessened and it is the time for her to make all the progress that she can by using all her expelling forces that she can summon. Teach her to take deep breaths and hold them firmly while pulling on the straps, and keep doing so as long as she feels the contraction of the uterus. The primipara often needs some coaching in the matter.

The patient may become sleepy and shirk the effort, if you do not insist on her doing her part, and thus prolong labor. I have had a few cases that I had to cure of the laziness by letting the heroin wear off and letting the pains come back with all their force. When I gave them heroin again they were more than ready to do their part. As I said before, some patients think when you offer them help that you must do all.

Remember that heroin produces analgesia and does not retard labor nor hasten labor itself. Get all the parturient forces to work and when you have once taught the patient to use those forces correctly then you can sit calmly by and watch the progress of the case. If dilatation is not far advanced I usually go and make calls if it is in the day time. At night I often lie down and rest. I come back to the case as often as my judgment tells me. If dilatation is nearly complete and labor well advanced I do not leave the case.

The effect of one injection of 1/12 grain heroin hydrochloride will usually last from two to three hours; I have had it last more than three hours. I have had cases that needed another injection in half an hour. When the head is dilating the vulva and perineum I aim to have all the effect of the heroin that the patient can stand without retarding the pains. A few times I have been so eager to produce perfect analgesia that I gave so much heroin that it retarded the pains. One-third or one-half ampule of pituitrin will start the pains if they become retarded. For a long time I was very positive that heroin did not stop the action of pituitary extract. Several of my friends told me that it did. They had given the latter frequently after heroin and other quieting drugs, and had found it of no assistance. A short time ago I had a few cases that I had well under control with heroin, and I wanted to hasten matters and I got no results even with a full dose of pituitary extracts. I was puzzled for a time, but on investigating I found that my druggist had given me another make. I sent for some of the old kind that I had used at first and I have been able to prove that it *will* work when I am having the patient under the full dose or heroin and does it properly. A few cases to illustrate my method:

Mrs. R., primipara, called me at 5 A.M., reported that membrane had ruptured, but that she had no pains. I told her to go to bed and call me when the pains started. At 7 A.M. she phoned that the pains had started. I saw her at 9 A.M. The pains were regular but not severe. Os rigid no dilatation (just such a case as I used to insert rubber bags). I told them to call again when the pains became more severe, and left to make other calls. At 11 A.M. I was called, and at that time found the pains very severe, and every 4 and 5 minutes in frequency. I gave ½ gr. heroin hydrochloride hypodermically. An examination revealed the os softening slightly. Again I made calls until 1:30 P.M., when I received word that the pains were severe again. I found the os as large as a 25-cent piece and softening very nicely. I gave another ½ gr. heroin and went to my office. At 4 P.M. I was called again. I found the os nearly dilated. I gave another ½ gr. heroin and instructed the patient to use her full parturition forces. She responded intelligently and labor progressed normally. At 6 P.M. gave 1/24 gr. heroin, and at 6:30 P.M. I delivered the child without laceration, either in the cervix or in the perineum. As I was leaving the patient I congratulated her upon standing the pains so well. She laughed and said, "Doctor, that was no pain at all. I am ready to have another baby at any time if that is all there is to it," yet she complained bitterly of the pains before I gave the heroin.

Mrs. W. By all the data and examinations she was nine and a half months parturient; she would have

slight pains almost every day but they were not lasting. I had confined her twice before—each time very slow but normal labors. Examination showed os soft and slightly dilated. I decided to induce labor. I gave 1/3 ampule pituitary; within fifteen minutes pains started vigorously every three or four minutes. When the pains became very severe I gave her 1/12 gr. heroin, which in this instance increased the frequency of the pain, but the analgesia effect was perfect. The patient was delivered in an hour and a half, absolutely normal, and with but very slight sense of pain.

Just after writing the above notes I was called to Mrs. C. Tripara; the membranes had been ruptured for two days. She had very slight pains once an hour or less often. I gave ½ ampule pituitary. Pains became hard and regular within ten minutes. After two hours the pains died down again. I then gave another ½ ampule pituitrin. Labor then progressed normally, and at the end of another two hours the os was fully dilated and the head passing down into the bony pelvis. As the head was passing the lower brim of the pelvis the patient began to complain of the pain. I gave her the usual 1/12 heroin and soon had perfect analgesia. The pains seemed of good quality but the progress was a little slow, so I gave another ½ ampule pituitary, and in fifteen minutes I delivered normally a 7½-pound child without laceration, and without the least outcry from the patient.

Mrs. S., primipara, had albuminuria for two weeks; some swelling of the feet and legs. No head symptoms. Pains off and on all night. At 7 A.M. I called and found the os slightly dilated. Pains not severe. Went away and came back again at 9 A.M. When the pains were very severe and dilatation was about two-thirds complete, I gave the usual 1/12 heroin hypodermically. In fifteen minutes she said she was dizzy but the pains did not hurt badly. I explained to her how to use her breath control and pull on the strap. She made very fine progress until the head engaged in the lower brim of the pelvis. I tried for an hour to make her deliver the child, but she could not. I put on the instruments and delivered the child at 12 M. had a very slight laceration of the fourchette. I gave her the first dose of heroin, 1/12, at 9 A.M. The next one at 10:30, another at 11 and another at 11:30. The last one slowed the pain some, but I had decided to use the instruments and wanted as perfect an analgesia as I could have. At the very last I gave a few whiffs of chloroform.

I have repeatedly delivered with forceps and used no chloroform, depending upon the analgesia from the heroin and had no outcry from the patient either. I rarely have to give an anesthetic to do repair work on the perineum if I have good analgesia at delivery from the heroin. The beauty of instrument delivery under the heroin analgesia is that the patient can and does assist in the expulsion of the child.

While writing the above sentences I was called in a hurry to a confinement case. Found the patient a primipara, yelling like a Comanche Indian on the warpath—with each pain. I gave 1/12 heroin at once. The head was just beginning to dilate the vulva. In fifteen minutes the patient took the pains without an outcry, and in twenty-five minutes I delivered an 8½-pound baby. Had a very slight laceration that required three stitches. Took the stitches without an anesthetic. The patient laughed when we had finished and said, "Those last pains were nothing at all compared with the pains I had when you came." I had given the hypodermic without an explanation, as the patient was a "Scientist," but her "healer" had not arrived to take care of the case and evidently absent treatments were not sufficient for the pains thereof.

If there is inertia of the uterus, quieting medicines will be of no use. I have made some good cases of inertia cases by using pituitary extract and when the pains got severe using small doses of heroin. I have never had a severe case of oligopnea where I used heroin. Last month I had a slight case of oligopnea, but in a few minutes the child cried lustily. I have had but one case of hemorrhage where I use heroin and that was instantly controlled. I have had ample opportunity to observe confinement cases where no drugs are used, as I am frequently called by members of two religious sects that forbid the use of drugs during confinement, and all the work must be done without anesthetics or any analgesics.

My observations have convinced me that oligopnea is most often produced by the head lying low in the pelvis for too long a period. The worst case that I ever had was in a Japanese woman where the Japanese midwife failed to deliver and I was called to deliver the child after the head had been low in the pelvis for several hours. I delivered without drugs of any kind and yet I worked a half hour before I could get the child to breathe well. My labor cases are shortened by the use of heroin for the mother uses better expulsive forces and dilatation takes place easier when under the use of this drug.

The shock after confinement is vastly less where heroin is used. In fact, shock is almost absent where the analgesia has been good. Patients rarely feel exhausted. I have given heroin in cases of valvular trouble of the heart, in albuminuria cases, in normal and abnormal cases. I have not had one bad result that I could trace to the drug.

PORTER BUILDING.

Medicolegal Notes.

Undertaking to Cure Incurable Disease.—The Oklahoma State Board of Medical Examiners revoked a license for being guilty of unprofessional conduct in undertaking, for a fee, to cure an incurable disease. On appeal, the Oklahoma Supreme Court held that the words "incurable disease," in the second clause of section 6905 Rev. Law, 1910, defining "unprofessional conduct" of a physician as "the obtaining of any fee, or the assurance that an incurable disease can be permanently cured," mean any disease which has reached an incurable stage in the patient afflicted therewith, according to the then general state of knowledge of the medical profession. A document was introduced in evidence headed, "Absolute Guarantee," in which the defendant agreed to refund all moneys paid by the patient should the latter fail to receive a complete cure by the treatment, and the patient agreed to follow the defendant's directions through a period sufficient as deemed by the defendant to effect a complete cure; failing his following the directions so given, the agreement to become null and void. The defendant claimed this was not a guaranty of cure, but only a guaranty to refund the fee in the event the treatment proved unsuccessful. The court considered this contract to be a mere subterfuge, probably drawn to protect the defendant in such proceedings; and that it in effect held out to the patient an assurance of a permanent cure.—Freeman v. State Board (Okla.) 154 Pac. 56.

Drugless Practitioners.—In a California court the argument was made that because the law includes such subjects as histology, elementary chemistry, toxicology, physiology, elementary bacteriology, and pathology in the examinations to be taken by applicants for certificates to practice as drugless healers, it is unfair, because these are standard courses of study in the preparation of physicians and surgeons, but are not needed in the art of those who intend to alleviate human suffering by manual and mechanical means only. The answer of the court was that to the Legislature is committed the duty of determining the amount and quality of scientific education necessary for the individual to possess before he may hold himself out to practice the healing art; but, while it was not for the court to substitute its discretion and judgment for those of the Legislature, the wisdom of some of these requirements for practice would strongly appeal to it, if it did possess a broader power than is given to it. For example, the importance of a study of toxicology is evident to every one. Without it the drugless practitioner might apply his manipulations to one suffering from the effects of a poison, and might continue his efforts until time for the successful administration of an antidote had passed. —People v. Ratledge (Cal.) 156 Pac. 455.

MEDICAL RECORD.

MORTALITY FROM ALCOHOL.

ANY estimate of how many deaths in a given community are due to alcohol must necessarily be open to question, in fact, the result must be taken after all as merely a guess, more or less shrewd according as the guesser is more or less clever. It is obvious that we must look elsewhere than on the death certificate for the information sought, for rare indeed is the occurrence of the word alcohol on one of these. Replacing it are more euphemistic names and ones less likely to involve the physician in unpleasant scenes with relatives or even possible libel suits. Even in the lowest class of patients there is a hesitancy about ascribing the death to alcoholism for it is just this class of patients which might sue a hospital or a physician with means, having everything to gain and nothing to lose.

Of course one way of guessing at an estimate of this sort is by ascertaining in what percentage of cases of a given disease alcohol is supposed to be a factor by clinicians. Then the number of deaths caused by that disease can be ascertained and it may be assumed that the same percentage of these deaths was due directly or indirectly to alcohol. This is the method adopted by Dr. Norman Porritt[1] in estimating the number of deaths in England and Wales during the year 1913, due directly or indirectly to the abuse of alcohol, which he places at 77,416. Conclusions arrived at in such a way are hardly worth putting on paper, but they will no doubt be widely quoted by the propagandists, in fact, have already appeared in one of their handbooks.

Among other diseases Dr. Porritt assumes that alcohol must have contributed to a varying proportion of the deaths due to cirrhosis of the liver, heart diseases, cancer, tuberculosis, and epilepsy. Without discussing any of these here except the last named, it may be said that we now speak of epilepsies rather than of epilepsy and that the old disease entity known as classical epilepsy is gradually shrinking to a comparatively small number of cases. There is absolutely no connection between alcoholism and idiopathic epilepsies.

The fundamental error in dealing with the problem of alcohol is the conception of it as a habit-forming drug, the abolition of which would mean the automatic regeneration of all inebriates. As a matter of fact, the inebriate is not normal and, deprived of his alcohol, would drift to some eleemosynary institution. This has been proved by the experience of prohibition States. We must not expect, however, to find any scientific view of the subject taken by publications such as the one in which Dr. Porritt's article appears, but instead the brandishing of such imposing arrays of figures as he has marshaled by not too critical calculations. The suggestion he makes that death certificates should be made confidential is one which admits of a wide discussion, but, while it might enlarge the number of reports of death due to alcoholism, it would still in all probability be far from accurate in this regard.

THE HOME TREATMENT OF TUBERCULOSIS.

ONE of the best results to be achieved by the campaign for the prevention of tuberculosis is the improvement in the sanitary conditions especially in such homes as are the most likely to have tuberculosis developed in them. With this in view there has in fact been everywhere created a demand for better, more cleanly, better ventilated, and better lighted homes. This demand has been making steady progress and the reduction of the new case incidence can well be attributed in large measure to this improvement of the home. But not so much in the prevention of the spread of one case to another has the improvement shown its strongest point, as in the creation of an atmosphere which reduces to a minimum the likelihood of the incipient cases rapidly passing on and through the other and final stages. It has the effect in curing a great many of the incipient unrecognized cases. Since Virchow enunciated his dictum of the universality of tuberculosis the fact has been brought home that many of the transient cases of influenza, common colds, attacks of bronchitis, and even "run-down" conditions are merely the evidences of the presence of mild transitory infections with the tubercle bacillus; and that the little extra care enforced during this period in the shape of rest, freedom from all forms of dissipation, good food, and the like soon overcomes these cases of mild, though masked, tubercle infection.

Because of the home conditions the treatment of the poor for tuberculosis has heretofore been an especially difficult problem. To treat them in uncleanly, congested, unventilated, and unlighted homes was out of the question; the private sanatorium was out of the question because of the very economic conditions which brought on the tuberculosis; and to wait for the public sanatoria to make room meant for most of them the arrival of their turn some time after death. In tuberculosis, even if nowhere else, does money mean life; for even if a sanatorium is attained the worry regarding the means to pay for this form of extravagance quite overbalances any good that might have been obtained through this form of treatment. The exiling of tuberculous patients to distant wilds and distant climes, away from every encouraging influence, and to be a burden upon strange communities, is a crime no longer countenanced by the pro-

fession or by the public at large. The superstition that a mad scramble to the farthest point away from home gave the surest and the most speedy hope of cure has no foundation in fact. On the contrary, it can be the greatest factor for harm. The overcrowding of certain communities having reputations as health resorts has a depressing influence on everyone. Healthy influences and the presence of healthy people seem to be among the best stimulants to the recovery from illness.

Whether from necessity or from other causes, medical men are fast seeing the possibilities of treatment with better results in nearby sanatoria, in domestic camps, or in the homes of the patients. The conversion of a previously insanitary home into a suitable one for treatment is not always an easy task, but with persistence and co-operation it can be done. The possibilities of the home treatment have been well illustrated by the results obtained by the Home Hospital established by the New York Association for Improving the Condition of the Poor. Their figures for cures are better than those of the best sanatoria. For the poor, the home hospital idea has decidedly the advantage over other methods because it adds to the well-being of the patients by permitting them to be near their dear ones, and often by giving them an opportunity to take advantage of any light occupation, when not contraindicated by their condition. Besides, one successful case of home treatment carrying out all the required hygienic demands of the disease is a factor of no mean proportion in furthering this campaign for the prevention of tuberculosis.

The addition of the day camp to the home treatment of tuberculosis has been a great improvement in such instances especially where home conditions could not be made acceptable. And when the night camp idea for patients in the incipient stage, who must do some form of work for their support, is added to the home idea in the treatment of tuberculosis, the results will nearly approach the ideal. When cases are diagnosed early the physician is now in position to advise against exile or expensive sanatorium treatment, and to assure a cure by home treatment of greater speed, more substantiality, and longer duration than he could hope for in any other way. There is no doubt that with proper home surroundings modelled especially for this purpose, with care exercised against infecting others, with the influence of home and friends, with proper food at the lowest cost, and with the addition of the day and night camps, cure and rehabilitation of the tuberculous by the home method may be obtained. And, particularly, the method encourages the maintenance of the highest sanitary ideals in the home after cure; where each case by the example set is rather a help to the community than a menace.

MISTAKES REVEALED BY THE PATHOLOGIST.

It has been conceded that the publication of diagnostic and therapeutic mistakes has much more teaching value than the narration of cures which may not have been cures at all but simple recoveries. The view has even been hazarded that a periodical devoted to mistakes would prove a huge success. This conception comes at once into violent clash with the principle that confession of failure is a weakness, and that prestige of the individual and profession would be irrevocably lowered by such a course. Upon such a foundation all the "antis" and others who are at odds with the profession would hasten to build. It is also evident that ordinary medical literature contains an abundance of data in reference to mistakes, introduced in their proper connection. No case could be properly reported without due mention of errors, timely recognition of which often leads to a successful outcome of the case; while proven neglect in recognition leads many to profit by the mistake of one. To raise the subject of errors to a special discipline is at least uncalled for.

The occasional publication of a series of errors upon a background of successes such as appears from the pen of Baetz in the *Journal of Tropical Medicine and Hygiene* for June 15, 1916, is always pertinent. The author covers five years of autopsy work, and arranges his material, with the exception of infections and neoplasms, by organs. Under the head of neoplasms, disseminated sarcoma was overlooked in four cases, masked respectively as dysentery, Pott's disease, syphilis of the liver, and congenital heart disease with visceral congestion. Under the head of renal disease we find that uremic eclampsia due to chronic diffuse nephritis masqueraded as epilepsy. A diagnosis of uremia ending in fatal coma was correctly made, but certain severe pains had received no explanation until autopsy revealed that the kidney mischief had all been due to an impacted calculus. A diagnosis of pyonephrosis was correct as far as it went but autopsy showed that the patient had but one kidney. In another correct diagnosis of chronic nephritis, it was found that the principal pathological condition was abdominal tuberculosis. Perforated duodenal ulcer with rupture passed in one case for lead colic, apparently a full fledged technical error. Another ulcer was overlooked in the presence of notable advanced cardiorenal disease.

It is hardly necessary to multiply these instances. The patients were negroes living in an environment of tropical diseases. The errors were seldom of the sort which cause death. The chief lesson to be drawn from them is not that of diagnostic fallibility, but of the great value of autopsies in all complex cases. These would greatly benefit the public if only they were made mandatory under a greater variety of conditions than that of sudden death.

The Infectivity of Poliomyelitis.

The epidemic of poliomyelitis which is now present in New York City and neighborhood is exciting undue alarm in consequence, no doubt, of the widespread publicity which has been given to it. To judge from the almost hysterical quarantine measures instituted in various localities—in staid old Connecticut of all places—one would think it as contagious as smallpox among the unvaccinated, or as yellow fever two decades ago. To quiet the ap-

prehensions of these timorous health officers the publication of authoritative articles, such as one appearing in *Public Health Reports* for July 14, 1916, is commendable. Dr. Wade H. Frost, past-assistant surgeon, U. S. P. H. S., writes here of the infectivity of infantile paralysis, summarizing in part as follows: "The rapid spread of epidemics over wide areas, their spontaneous decline after only a small proportion of the inhabitants have been attacked, and above all the preponderating incidence in young children, have not been satisfactorily explained by any hypothesis other than that the infective agent during epidemics is widespread, reaching a large proportion of the population, but only occasionally finding a susceptible individual, usually a young person, in whom it produces characteristic morbid effects. Assuming this rare susceptibility, the well-established facts collected by epidemiological students are compatible with the evidence of laboratory experiments that the disease is directly transmissible from person to person." On the whole, perhaps, this is the most reasonable manner of regarding the infectious nature of poliomyelitis. Only a comparatively few persons are susceptible and these are, with few exceptions, children, the susceptibility being generally greatest in the first half decade of life, thereafter progressively diminishing until in adult life there is a very general immunity to natural infection.

Autotherapy.

The general principles of autotherapy, as first described in the Medical Record, are formulated by Dr. Charles H. Duncan as follows: "When the pathological exudate, or the end product, or a dilution of the same, of any localized (and possibly nonlocalized) infectious disease is filtered with a Berkefeld filter and the filtrate injected hypodermically, or placed in healthy tissues, antibodies specifically corresponding to the disease, will tend to be developed." A corollary of this general rule is: "In extra-alimentary and extra-pulmonary diseases, if the crude pathological end products are placed in the mouth specific resistance to the disease will tend to be developed." This method is reviewed at length in a recent issue of the *Southern Medical Journal* by Passed Assistant Surgeon John C. Parham, U. S. Navy, who points out that in many cases of infection and especially in some types of skin infection autogenous filtrates act almost magically. Parham is of the opinion, judging chiefly from his own experience in treating cases of infection by autotherapy, that in surgical as well as in medical fields its range of application is wide, and, what is to the point, it is effective. It is obvious that the secretion of a wound upon which an antiseptic or germicide, such as bichloride, phenol, etc., had been used would be unsuitable. However, he believes that the day of these agents so generally employed in surgical practice is on the wane, and that the almost universal use of salt solution, salt solution and sodium citrate, or Wright's solution will supplant them. These solutions, not being antiseptics or germicides, are not contraindicated where the employment of autotherapy is anticipated. If by means of autotherapy active immunity can be acquired in cases of infection, then there can be little doubt that as a method of treatment it will quickly make headway, although there are still many points in connection with the method which require further study and elucidation.

Vincent's Method of Prophylaxis and Infantile Paralysis.

Vincent of angina fame once published a thorough method of disinfection of the upper air and food passages which has been used extensively in the prophylaxis of cerebrospinal meningitis, grip, anginas, etc. Quite recently Coulomb applied it to 600 soldiers, each of whom rinsed his mouth and gargled his throat with iodized water or Labarraque's solution 50 to 1,000. Under a couple of days' use the daily number of anginas reported fell to zero. When cerebrospinal meningitis was epidemic and all other methods had failed to arrest the outbreak, that of Vincent was applied intensively with great success. The particular antiseptic used is apparently less essential than the manner of using. Three times a day after meals a preliminary douching of the entire mucosa with 10 per cent. hydrogen peroxide was carried out. The tonsils and pharynx were afterwards painted with iodine 10 parts, potassium iodide 10 parts, and glycerin 300 parts. Further, three times a day each soldier inhaled the following: Iodine 20 gm., guaiacol 2 gm., thymic acid 0.25 gm., alcohol (60 per cent.) up to 200. The inhalation should last two minutes. At a later period the disease reappeared, and 107 suspects were isolated, 15 of whom were found to be meningococcus carriers. Vincent's method was used for four consecutive days and after two days of intermission the throats of all the men were found sterile, while not a case of meningitis had developed. These data are taken from an article by Lefas in *La Presse Médicale*, June 29. There is no mention of acute anterior poliomyelitis, but it would seem that the article ought to be timely in connection with the present local epidemic of the latter. The combination of douching, brush application, and inhalation should sterilize all ports of entry. On account of the tender age of most of the victims the method would perhaps have to be modified.

News of the Week

The Poliomyelitis Epidemic.—There has been little change in the epidemic of infantile paralysis in New York and vicinity during the past week, except that the number of new cases in Brooklyn where the epidemic began is decreasing, showing apparently that the susceptible material in that region is nearly exhausted. Health Commissioner Emerson has called a conference of pathologists and bacteriologists for Thursday of this week to study the epidemic and suggest possible measures for its control. Those invited are: Drs. Victor C. Vaughan, University of Michigan; Milton J. Rosenau, Harvard; Dr. J. W. Jobling, Vanderbilt University; Paul A. Lewis, University of Pennsylvania; John Howland, Johns Hopkins University; C. C. Bass, Tulane University; Theobald Smith, Princeton; John F. Anderson, New Brunswick, N. J.; Richard M. Pearce, University of Pennsylvania; Francis W. Peabody, Peter Brent Bingham Hospital, Boston; Ludwig Hektoen, University of Chicago; John G. Adami, McGill Medical College, and the following from New York City: Drs. Simon Flexner, Hideyo Noguchi, Hans Zinsser, George Baehr, Francis Carter Wood, William J. Elser, William H. Park, and C. H. Lavinder and Wade A. Frost of the United States Public Health Service. The total number of cases up to August 2 was 4,123 and of deaths, 898.

An Experiment in Tuberculosis Control.—The National Association for the Study and Prevention of Tuberculosis is about to institute an experiment on a large scale for the control of tuberculosis. It is proposed to select a town of from four to ten thousand inhabitants and then to discover with the aid of the local physicians, through careful medical examinations every case of tuberculosis, every individual who has been exposed directly to the disease, and particularly all children up to sixteen who have had close relations with persons ill with tuberculosis during their lifetime. It is proposed that every known case of tuberculosis and every exposed case of whatever nature should be under some sort of supervision during a three-year period, either in the home, in an open air school, in a tuberculosis clinic, or in a hospital or sanatorium. In this way and by keeping in close contact with all new families and new babies born into the community the committee hopes to be able to prevent the spread of tuberculosis, to stop the development of any new cases in the community, and to determine the absolute and relative worth of the various methods usually employed in fighting the disease.

Anthrax in Western New York.—A meeting of representatives of the dairy industry of Erie County and officials of the State Agricultural Department was held recently in Buffalo to discuss methods to check the outbreak of anthrax among herds in several of the towns of Erie County. About thirty authentic cases of the disease have been found. The animals were slaughtered and buried in quicklime. One farm hand is known to have contracted the disease.

A Large Sanatorium Planned for Hot Springs.—It is announced from Hot Springs, Ark., that capital is being raised in New York for the erection of a large sanatorium at that place. The building and grounds will occupy ten acres and will cost $9,000,000.

Trouble in a Pittsburgh Hospital.—A disagreement between the medical staff and the superintendent of the Presbyterian Hospital in Pittsburgh has resulted in the resignation of three of the attending physicians. The superintendent also resigned, but her resignation was not accepted by the trustees, who passed a resolution of confidence in her and satisfaction with her work. The medical men assert that the management of the hospital was more anxious to make money for the institution than to help the sick poor, and that the wards were filled with pay patients to the exclusion of those who could not pay. The trustees declare that these charges are unfounded.

More Hospitals Needed in France.—William P. Hollingworth, Vice-President of the American War Relief Clearing House for France and Her Allies, who recently returned to this country, reports that there is an urgent need for more hospital and ambulance groups for the French Army manned by American volunteer drivers. The French Government has shown high appreciation of what has been already done in this direction. The work of relieving the refugees and the distribution of hospital supplies undertaken by the War Relief Clearing House has reached enormous proportions. About 40,000 cases of clothing and supplies have been shipped to France and distributed through the Clearing House in Paris, besides many thousands of dollars in money.

Dr. Straw Honored.—Dr. A. Gale Straw, a member of the Harvard medical unit on active service at the front in the European war, has been promoted from the rank of captain to that of major for efficient service.

Dr. Albert Neisser, Professor of Dermatology at the University of Breslau, and discoverer of the gonococcus, died on July 30 in his sixty-second year.

Milk for German Babies.—The State Department at Washington has received a cable from Dr. Taylor of the American Embassy in Berlin, stating that the report published in New York that the babies in Germany are suffering for lack of milk is not true. He has made a special investigation throughout Germany, at the request of our Government, and finds that, instead of a diminution, there has been an actual increase in the milk supply. As further proof that the babies are not starving it is stated that the infant death rate in Germany is now lower than it was before the war.

Praise for American Red Cross Nurses.—Mr. William Warfield, formerly an attaché of the American Embassy in Petrograd, and now chargé d'affaires for the United States in Sofia, Bulgaria, has written to Miss Jane A. Delano, chairman of the National Committee on Red Cross Nursing Service, as follows: "While acting as an attaché of the Embassy in Petrograd, specially assigned to war relief work, I had occasion, as you know, to see a great deal of the members of the American Red Cross units in Russia. It gives me great pleasure to take advantage of this opportunity to say that the nurses attached to these units have been the greatest credit to the organization and to the country they represent. Their professional efficiency is not only unquestioned, but has excited a great deal of comment in medical circles, having been mentioned to me frequently by the Russian surgeons. Personally, by their devotion to duty and their splendid organization and discipline, these ladies have been a credit to American womanhood and its ideals. I do not hesitate to say that they have had an influence for good quite apart from mere professional services."

Lecturers on Dentistry for Medical Students.—Announcement is made of a special series of lectures on dental subjects to the students of Columbia's Medical Department during the coming year. The course of lectures will aim to furnish the medical student with a knowledge of the fundamental principles in the proper care of the teeth and will emphasize the close relation between the diseases of the body and defective teeth. The lectures will be given by Drs. Arthur Merritt, Leuman M. Waugh, W. B. Dunning, H. S. Vaughan, and Henry S. Dunning.

New Naval Surgeons.—At the recent examination the following named medical men successfully passed for appointment as assistant surgeons in the Medical Reserve Corps, with a view to subsequent examination for appointment in the Medical Corps of the Navy: Drs. James A. Halpin, Washington, D. C.; William D. Heaton, Wahoo, Neb.; Aubrey M. Larsen, Salt Lake City, Utah; Lincoln Humphreys, Argenta, Ark.; Theo. Edward Cox, Cleveland, Ohio; Arthur W. Hoaglund, Minneapolis, Minn.; Carroll H. Francis, Camden, N. J., and Harold L. Jensen, San Francisco, Cal.

American Electrotherapeutic Association.—The next annual meeting of this association will be held at the Hotel Martinique, New York City, on September 12-14, under the presidency of Dr. Jefferson D. Gibson of Denver. The secretary is Dr. Byron S. Price, 65 Central Park West, New York.

The Northwestern Medical Society of Nebraska

held its annual meeting in Canyon Park, Long Pine, on July 18, at which time the following officers were elected: *President*, Dr. G. O. Remy, Ainsworth; *Vice-President*, Dr. E. T. Wilson, O'Neill; *Secretary*, Dr. J. M. Tische, Wood Lake; *Treasurer*, Dr. Thomas J. Lawson, Long Pine. Wood Lake was selected as the place for holding the next meeting, the last Tuesday in October.

The Montana Medical Association held its annual meeting on July 12 and 13 at Miles City, electing the following officers: *President*, Dr. J. A. Donovan, Butte; *First Vice-President*, Dr. Arthur Morrow, Kalispell; *Second Vice-President*, Dr. R. H. Beach, Glendive; *Third Vice-President*, Dr. Arthur Jones, Butte; *Secretary-Treasurer*, Dr. E. J. Balsam, Billings. The next annual meeting will be held at Kalispell.

The Study of Inebriety.—A Research Foundation has recently been organized at Hartford, Conn., for the purpose of making an exact scientific study of the causes of alcoholism and inebriety. It will be endowed and become a permanent work. Preliminary studies have already begun, and practising physicians from all parts of the country are appealed to for the records and histories of cases which will be compiled and tabulated for the purpose of determining the laws which control and govern them. Dr. T. D. Crothers of Hartford writes that this is the first scientific effort to take up the subjects of alcoholism and inebriety and determine the causes which produce them outside of alcohol. Science has shown that these conditions are governed by exact physical and psychical laws, which if known and understood would indicate the most practical means and measures of relief. The Foundation will be practically a laboratory or clearing house, where persons can come for examination, counsel, and advice. To a large class of persons who want something more than pledges, appeals, or sanatorium treatment this will open a new field of means and measures for relief that will be most welcome. Among the questions, an answer to which will be sought, are the following: Why are certain periods of life more favorable for the outbreak of the craze for alcohol than others? Why does the desire to drink break out suddenly in diverse conditions and then subside from causes inadequate to explain the change? What is the explanation of the exact periodicity of these drink excesses that are as certain as the rise and fall of the tide? What are the causes in surroundings and conditions of living that provoke these paroxysms? Why do men drink after injuries, diseases, shocks, losses, disappointments, business reverses, and great successes in life? What degenerations are transmitted from the parents to the children that create susceptibility or immunity to the effects of alcohol? Why are some persons able to drink in so-called moderation for years and why do others quickly become diseased and die? Why do some men drink in early life, then abstain, and in middle or later life turn to alcohol again and drink until death? Why are some persons susceptible to the contagion of surroundings and companions, while others are immune? What physical and psychical causes produce the drink craze?

Obituary Notes.—Dr. William McKelvy of Denver died July 13 at the age of 62 years. He was a graduate of the medical department of the University of Pennsylvania in the class of 1875 and practised in Breckenridge, Colo., from 1880 to 1900, when he removed to Denver.

Dr. E. W. Dean of Hiram, Ga., died in Atlanta on July 4. He was a graduate of the Medical Department of the University of Georgia in the class of 1883.

Dr. David William Edgar of Ames, Iowa, died suddenly in Marshaltown on July 8 at the age of 71 years. He was born in Wisconsin and was graduated from Rush Medical College, Chicago, in 1874. He practised at various times in Monroe and Dayton, Wis., and Gowrie and Fonda, Iowa. On account of heart trouble he retired in 1911 and went to Ames to live.

Dr. Roscoe Smith of Auburn, Me., died on July 8, after a month's illness, at the age of 80 years. He was born in Peru, Me., and was graduated from the Harvard School in 1869. He practised for many years in Turner, retiring in 1889, and subsequently removing to Auburn.

Dr. Louis Augustus Woodbury of Groveland, Mass., died July 17 at the age of 72 years. He was born in Salem and was graduated from the Harvard Medical School in 1872. He was a member of the Harvard Alumini Association, the Haverhill Medical Club, the Massachusetts Medical Society, and the American Medical Association. He retired from practice about five years ago.

Dr. James Smiley Bush, Jr., of Colquitt, Ga., died in Albuquerque, N. M., on July 13, at the age of 31 years. He was born in Colquitt and was graduated from the Atlanta College of Physicians and Surgeons in 1912. He was obliged to give up practice about a year ago on account of ill-health.

Dr. Thomas C. Elmendorf of Port Chester, N. Y., died recently at his home in that place at the age of 64 years. He was a graduate of the New York Homeopathic Medical School and Hospital in the class of 1875.

Dr. James F. Heady of Glendale, Ohio, died on July 24, after a long illness, at the age of 64 years. He was born at Vevay, Ind., and was graduated from the Miami Medical College, Cincinnati, in 1878. After an interne service in the Cincinnati General Hospital he began practice in Glendale.

Dr. Thomas Alphonzo Kenefick of New York and Newport, R. I., died at the home of his brother in Lawrence, Mass., on July 30. He was born in 1858 and was graduated from the Medical Department of Columbia University in 1885. He was a member of the Rhode Island Medical Society, of the Medical Societies of the County and State of New York, of the American Medical Association, and of the New York Academy of Medicine.

Dr. Herman G. Tarter of Chilhowie, Va., died at the residence of his father, Dr. J. E. Tarter of Wytheville, on July 15, at the age of 31 years. He was a graduate of the Medical College of Virginia in Richmond in the class of 1911.

Dr. Price Emerson Murray of Atlanta died July 20 at the age of 63 years. He was a graduate of the Atlanta Medical College in the class of 1886.

Dr. William Lovett of Norman Park, Ga., died after a brief illness on July 21, at the age of 34 years. He was born in Sparks, Ga., and was a graduate of the Atlanta College of Physicians and Surgeons in the class of 1913.

Dr. Adolfo Lamar of Havana, Cuba, died in New York City last week, from disease of the heart, at the age of 47 years. He was a native of Havana and a graduate in medicine of the University in that city.

Correspondence.

MERCURIC SUCCINIMIDE IN POLIOMYELITIS.

To the Editor of the Medical Record:

Sir:—Owing to the continued and virulent epidemic of infantile paralysis in New York, a condition that demands the use in the treatment of the disease of any method which has the remotest possibility of being of value, I venture to suggest that the method advocated by me since 1910 for the treatment of many of the acute infectious diseases, namely, deep intramuscular injections of large doses of mercuric succinimide, should be tried.

Barton Lisle Wright, M.D.,
Surgeon, U. S. Navy.

U. S. S. Delaware.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

HONORS FOR MEDICAL SERVICE IN THE FIELD—STRANGULATION OF THE UTERUS BY TORSION—FIBROMA—SUPRACERVICAL HYSTERECTOMY.

London, July 8, 1916.

Among the recent honors for services in the field the C. B. has been conferred on Col. F. W. G. Gordon-Hall, M. B., A. M. S., and Lieut.-Col. R. J. W. Mawhinery, R.A.M.C. and the C.M.G. on Major A. C. Valadier, A.M.S. The distinguished service order is awarded to Major Robert Tilbury Brown and Lieut.-Col. A. E. Conquer Keble, and the Military Cross to Corporal Morton Peto and J. Swinburn Townley. The Commander-in-Chief, East African Force, Lieut.-Gen. the Hon. J. C. Smuts, has transmitted a list of officers recommended for services in the field, a considerable proportion being in the Royal Army Medical Corps, the South African, and the Indian Medical Services.

There is a shortage of medical recruits for the army which is expected to continue for some time and perhaps increase. Under the new act calling-up notices are not being sent to men who have two or more children. This will apply to 178 officers, of whom 93 are on the panel. It is said that of these 31 are entitled to exemption, but it is hoped that they will remain and that others who have so far kept off will come forward to help in the present emergency.

The act came into operation on the 24th ult. and makes every medical man under 41 years old a soldier unless he has enrolled with the Central Medical War Committee. An appeal by the authorities for more men even up to 45, has been readily responded to and it is expected that a further appeal will be made—probably up to 50 or even 55, and it is certain that many of that age are capable of effective service. There has been some hesitation on the part of practitioners on account of the inadequate statement as to what was to be the duties undertaken. A physician is not willing to be put over a surgical ward and vice versa, and the Central War Committee should see that every one they induce to come to their help should be assigned to the work with which they are most familiar.

At the Obstetrical Section (R. M. S.) Mr. J. D. Malcolm showed a case of strangulation of the uterus by torsion of the body on the cervix. A frail lady of 70, married but never pregnant, was seized with pelvic pain after dinner. Next morning took breakfast as usual, but could not get up as the pain increased and vomiting came on. Temperature by evening reached 101° F. Seen by three doctors late that night, a hard, round, pelvic tumor about 4 inches in diameter was felt in the median position. Behind this was an irregularly oval mass about 3½ inches from above downward by 1½ inches from side to side, uneven in consistence, but most of it fairly soft. Below was a soft short cervix uteri. The rectum was firmly compressed, but slightly movable as a part of the pelvic mass. A fibroma had existed before menstruation ceased and it seemed as if something had twisted, but the condition behind the hard tumor was a puzzle. The abdomen being opened a fibroma was seen attached to the left anterior upper part of the uterus. This and the uterine body had revolved a full turn on the cervix; the lower end of the body was tightly twisted, the parts above being of a deep, blue-black color, and although it was only 28 hours from pain being felt and only 16 hours after it became severe, there was a distinctly offensive odor. Supracervical hysterectomy was performed; the left ovary and tube were raised by the new growth above the constriction and they were removed; the right were below it and were not taken away. The recovery was slow but otherwise good. The specimen was exhibited, the uterus body was obviously enlarged by congestion, was soft from age and the softness with its attenuation permitted the strangulation by torsion. Dr. Cuthbert Lockyer was glad the case was brought forward, as it demonstrated a rare condition which presented great difficulties in diagnosis. As to the torsion, it was known that a twist of the corpus on the cervix through as much as 90° could occur without producing symptoms suggesting the condition. In eight cases of torsion recorded by Kelly and Cullen not one set up special symptoms, and in one of them the corpus was rotated through 180°. The torsion usually is through the isthmus which gradually atrophies and forms a sort of pedicle for the body above it. This pedicle may become severed from the cervix, as shown in a case of Bastinelli of Rome. Dr. Lockyer referred to five recorded cases of acute torsion, the causation of which is still a subject of speculation.

OUR LETTER FROM ALASKA.

(From Our Special Correspondent.)

"SEE ALASKA FIRST."

St. Michael, July 6, 1916.

This letter is written with the view of inviting the attention of the professional man who is thinking of a trip to the fact that Alaska offers some very interesting features for the professional man and its scenery stands in a class by itself. The transportation companies have so perfected their means of travel that a trip through Alaska is now a luxury instead of a hardship as in former times.

The average person of the United States knows very little of the vastness of this territory which in square miles is said to equal New York, New Jersey, Pennsylvania, Illinois, Indiana, Ohio, Michigan, Wisconsin, North and South Dakota, and all of New England combined. If a map of the territory was superimposed upon that of the United States—drawn to the same scale—it would extend from Charleston, S. C., to San Francisco. This vast country extends from about 55° to about 71° North latitude, or more than 4° north of the Arctic circle, and with this vastness is a great diversity of climate, scenery, flora and fauna.

The climate of Southeastern Alaska is much like that of Oregon while the climate of Northwestern Alaska more nearly resembles that of northern Montana, but even in this comparison the extremely short days in winter and the extremely long days in summer mark quite a contrast. In summer this truly is "The Land of the Midnight Sun." The winters are pleasant, but as the only means of transportation is by the dog sled, winter is a poor time to visit Alaska; but with the advent of summer the geese, duck, swan, crane, and many varieties of smaller birds return by the millions and there is probably no place where more game can be seen to the square mile than in Alaska from May until October. The flora too is interesting. The surface snow and ice disappear and the fields that are at first bleak and barren looking, soon take on a very picturesque appearance with wild flowers of every color and many varieties.

The glaciers, rivers, plains, seas, islands, volcanoes, mountains, tundras, forests, fishing, hunting, and mining (especially for gold) will keep the average tourist's attention from the time he first sights southeastern Alaska until he passes through the Unimak pass of the Aleutian Islands, on his homeward journey. But for the professional man there is still more of interest! The Eskimo, as the native is called who lives on the coast, and the Indian, who lives in the interior, offer a vast field for medical study. On account of the climatic conditions, isolation, and environment, the native has acquired many habits that are unknown within the United States. Of the many interesting things that these people offer, the following seem most strange: Their method of burial in improvised boxes above ground, covered with logs on which are fastened the belongings of the deceased, their method of dress, what they eat, their houses, their methods of transportation in summer (kyack) and winter (malamute dogs and sleds), the council house (kashim), the "medicine man" and a talk with him and possibly seeing him "make medicine" (treatment of the sick by song and dance), or possibly the witnessing of some festivity as "The Feast to the Dead."

When a doctor visits a native village for the first time he will most probably say or think "My! I had no idea that these people were in such great need of medical and surgical treatment! What a vast field this offers for some missionary or other kind of benevolent society." "How dirty they are," will probably will one of the first remarks made. The doctor will be struck with the large number of persons who present evidences of tuberculosis both pulmonary and of the spine, also with the large number of cases of skin diseases, the large number of persons who live in each house (which house is usually of one room), and the large percentage of children. If possible, he should go into some of these houses and try to see some of the natives at meal time. It is not customary to knock, but to walk right in and say "wah-kah" meaning "How do you do?" He will almost always find the women or squaws at work, but will very rarely find the men doing anything.

Some of the most interesting things that the doctor will see in southeastern Alaska are the totem poles which are records of family deeds and achievements and vary from small sticks to enormous poles. Some of the most interesting things that he will see in northwestern Alaska are the beautiful and useful things that the natives carve from walrus ivory and mastodon ivory. In fact he can get almost anything he desires made of this material, and if the time will permit can have it made to order. Of course Alaska is noted for its furs; mink, martin, otter, swan's down, eider down, lynx, red fox, white fox, cross fox, ermine, and beaver are on the market and handled by the fur traders and merchants. The price will be about the same as paid in the United States but one will have a greater selection to choose from. All furs seem high this season.

In making out an itinerary I would suggest the following: Purchase a round trip season ticket from your home to Seattle, arriving in Seattle about two days before the ship is scheduled to sail. Procure a round trip ticket to St. Michael reading through the Inside Passage and down the Yukon river to St. Michael, from St. Michael to Seattle via Nome. This will give an ocean trip to Skagway through the beautiful inside passage. Take the train at Skagway for Whitehorse (Canada) over a railroad that stands in a class by itself, and connect with a river boat for Dawson and Tanana and change for St. Michael. This gives a river voyage of about 2,000 miles touching at many points and usually long enough for passengers to go ashore and see what is to be seen.

It is estimated that the trip above outlined will take about thirty days and cost approximately $270 including transportation, meals, and berth, but $400 should be allowed for the trip to cover the cost of incidentals and for the purchase of interesting and useful souvenirs. This is the complete trip, but there are many shorter trips, in fact any point along the line may be used as the turning point and thus shorten the time for the busy professional man. There are good accommodations for ladies and children and nurses. The summer temperature varies from about 50° to 68° Fahr. and along with the ocean trip it is thought that such a trip will prove to be helpful to children suffering from intestinal troubles as well as possibly many others.

The professional men of Alaska are cosmopolitan, interesting, and cordial and I believe will be pleased to devote a portion of their spare time to meet our professional brothers and to show them points of local interest. One need have no hesitancy in introducing oneself and feeling sure of a welcome in the office of any physician who practises in Alaska.

3. Epidemic Poliomyelitis; The Symptomatology and Diagnosis in the Acute Stages.—Francis R. Fraser states that in the preparalytic period and in abortive cases the diagnosis of poliomyelitis depends, to a great extent, on the presence of an epidemic and association with other cases. Under these circumstances, a history of sudden onset, with fever, gastrointestinal symptoms,

and perhaps pain, would indicate a careful examination for signs of stiffness of the neck and back. If any suspicion of a meningitic lesion is entertained, lumbar puncture must be performed, when the condition of the spinal fluid will clear the diagnosis in most cases. The differentiation from a gastrointestinal upset is most difficult, but in gastrointestinal disorders the spinal fluid is normal. Other common infectious diseases commence similarly, but in them the pain and hyperesthesia are usually absent. Skin lesions in poliomyelitis have been described, but are not constant in character, and are present in only a small number of cases. Acute rickets is easily mistaken for poliomyelitis because of the fever, the prostration, and the tenderness. The spinal fluid, however, is negative, and in poliomyelitis pronounced enlargement of the liver is not found. Tuberculosis of the hip can be differentiated by the history of onset. Acute rheumatic arthritis may commence acutely, and the fever, pain, and disinclination to move, be very similar; but the tenderness is localized to the articular structures, and in poliomyelitis there is no swelling of the periarticular structures and no synovial effusion. Meningitis due to the meningococcus, the pneumococcus, the influenza bacillus, to streptococci and staphylococci, give a spinal fluid with increased cell count, due to polymorphonuclears, and the causal organism can be found in the smears and can be cultivated. In tuberculous meningitis and syphilitic meningopyelitis, the spinal fluid is very similar to that of poliomyelitis, and the clinical findings do not differentiate it until the case has been watched for a few days. A positive Wassermann in the blood is not sufficient to differentiate syphilitic meningitis, as it may be found in acute poliomyelitis, as in other acute infections. Even when evidence of paralysis, or of involvement of the motor system, is found, the diagnosis may not be clear. Acute poliomyelitis is probably more often mistaken for cerebrospinal meningitis than for any other disease, especially as paralysis may occur in both; but the rash, the photophobia, and characters of the spinal fluid, should differentiate them.

4. **Anatomic Form and Posture Important Factors in the Treatment of Pulmonary Tuberculosis.** — Joel E. Goldthwait calls attention to the different anatomic types that exist, and to the fact that each type has its own more or less definite potential of disease, and of these the congenital visceroptotic, the carnivorous, the hyper-onto-morph, is commonly tuberculous. This type, during development, acquires habits of carriage in which the ribs are lowered and the chest is used in the position of full expiration. In this position, thoracic breathing must be very imperfect and full expansion of the chest rarely occurs. The writer describes several defective anatomical types, and shows how they interfere with the mechanism of breathing and the function of the heart. From these he draws the practical suggestion that if we are to do the best we can to insure health we must see that the body is so used that the rhythm of respiration, both as it refers to the thoracic and the diaphragmatic movement, is as nearly normal as possible. With the facts thus brought out, the use of a back brace for a case of pulmonary tuberculosis may seem unusual, but is not irrational. In the treatment of tuberculous patients, the importance of posture must be borne in mind at all times, and particularly as the patients are put out in the open to get the fresh air. If improperly propped up in bed, obviously little air can get in to the individual, and this is also true of some of the reclining chairs which are used in our sanatoria, especially the canvas steamer chair. If such chairs are used, their harmful features should be appreciated, and corrected. The simple use of a board placed at the back of a canvas steamer chair makes the chair much less objectionable. The aim in treating these patients should be to make the full excursion of the chest in inspiration and expiration possible with the least effort.

5. **The Teaching of Therapeutics as a Branch of Applied Physiology.**—F. H. McCrudden expresses the opinion that the teaching of therapeutics is one of the weakest points in the training of the medical student. He thinks that a division of medical science dealing with the aims and methods of therapeutics, and filling in the gap between physiology, chemistry, physics, pharmacology, and the other fundamental sciences which underlie the methods of treatment, on the one hand, and the actual details of treating individual patients from day to day, on the other, should be recognized, and a course on this subject should be added to the medical curriculum. This instruction should aim to give the student a point of view regarding these purposes and principles of treatment, so that these details may be contemplated not as a vast number of empirical and unrelated elements, but as mutually dependent parts of a whole. It should continue the emphasis on scientific habits of thought, which is one of the objects of instruction in physiology and other fundamental branches of medical science, and bring out the fact that therapeutics is not an empirical art, but an applied science. The writer emphasizes the importance of impressing students early in their medical career with an optimistic and hopeful attitude toward the result of treatment. The less optimistic attitude of many physicians is due not to the poor results of treatment, but to discouragement at the difficulties of having treatment carried out in private practice, a distinction that should be brought home to the student. For an understanding of rational therapeutics a study of the treatment of chronic disease forms the best basis.

7. **A Review of 127 Clinical Cases of Ataxia Paraplegia.**—G. H. Bigelow bases this study on the records of the Neurological Clinic of the Massachusetts General Hospital, from 1903 to 1915. He finds that of these 127 cases of ataxia paraplegia, 70 per cent. were males, whereas in the whole Out-Patient Department approximately 58 per cent. are males. In 83 cases, a possible etiology was established. This was as follows: Syphilis, 43; following accident, 10; following acute infections, 6; hemiplegia, 5; alcoholism, 5; malformations or irregularities of the spine, 3; hypertension, 3; chronic disease, 2 (gout and sepsis); exhaustion, 2; anemia, lead poisoning, neurotic family history, exposure, heredity, tumor, pellagra, each 1. In 44 cases no possible etiology could be found. Of the 47 syphilitic cases, only 7 showed positive laboratory findings. The essayist concludes that, contrary to the observations of several other authorities, it would seem from an analysis of these cases that syphilis is an important etiological factor in ataxia paraplegia.

4. **Percussion in Early Tuberculosis.**—Julius Schneyer says that there is no doubt that some change of resonance to gentle percussion accompanies very early

lesions in the apex; indeed, it is his experience that some alteration to skilled percussion can be found in every diagnosticable lesion, and that diagnosis can rarely be made without it. He concludes that impairment of resonance in one apex can be discovered by the softest percussion, having in mind the possibility of hypersonance on the opposite side. Reinforcement by expiratory percussion may be tried in doubtful cases. These cases are often overlooked or missed if ordinary percussion is used. The degree of impairment may be determined by increasing the weight or force of percussion in order to see if it still persists, or at what point it stops. The most important evidence for diagnosis is the finding whether there is any impairment at the other "seats of election" for tuberculous deposits, for instance, in the opposite side or at the apices of the lower lobes. Topographical percussion may supply us with the following information: *a*, Equal resonant areas and of normal extent are evidences of normal lungs. The areas of normal measurement, but one being displaced, is a condition described by Kroenig under the name of "physiological heterotopia." It was this condition which led Kroenig to discover his outer boundary. *b*. There may be a blurring of one or the other, or both margins of the resonant area, with or without some general loss of resonance, a condition very suggestive of early tuberculosis. *c*. A difference of the areas and especially in the width of the "isthmus" may be due either to expansion of one side, or retraction of the other, or both conditions may be present. Auscultatory percussion, as practised by the writer, has proved of notable value for the confirmation of the findings by gentle percussion in outlining Kroenig's areas, or mapping out the respiratory excursion of the lung borders, especially when external noise prevents appreciation of the delicate shades of difference in sounds by gentle percussion. The diminution of the respiratory excursion of the lower border of one lung is an early sign of tuberculosis, emphysema, old age, pleurisy, pain, inability to breathe, or other conditions interfering with the free movement of the lung in the pleural space without active disease having been excluded. As a measure of the extent of pleurisy in any case of phthisis, in order to decide as to the advisability of artificial pneumothorax, the measurement of the degree of movement or expansion of the lung is of notable value.

6. **Intraperitoneal Adhesions.**—R. J. Behan and W. A. Nealon present the results of a study made to determine the cause of the intraabdominal formation of adhesions and the manner of their prevention. They have made observations to determine if alcohol, glycerin, denudation, infection (mild or severe), or toxins or bacteria passing out from the intestines, can form adhesions. They have also made studies to determine if petrolatum applied over raw areas will retard adhesive formation; whether wool fat, an organic fat alone, or mixed with some inert or soluble substance as boric acid, inhibits adhesion formation, and whether olive oil or Russian oil prevents or hinders adhesive formation. In the course of their investigations it became apparent that something more than traumatism was necessary to the production of adhesions between two adjacent peritoneal surfaces. This additional factor may be infection of a mild type. The previous methods of preventing adhesions apparently did not take sufficiently into consideration either the possibility or the presence of this infection; and also discounted another important factor, namely, that in using olive oil or mineral oil, such as petroleum, a foreign substance was being introduced into the peritoneal cavity, the reaction to which would be the throwing out of an exudate with fibrin deposit and subsequent adhesive formations. In the hope of deriving some information along these lines experiments were performed with wool fat and boric acid as an antiseptic to counteract any mild infection which should occur in the abraded peritoneal cavity. The results of these experiments on animals were so encouraging that these observers decided to try wool fat boric acid paste in the human abdomen. Thus far they have used it in fifteen cases with good results. Up to the present time none of these patients have complained of symptoms which could be traced to adhesions, though sufficient time has not elapsed to determine whether the tendency to adhesive formation has been entirely obliterated. In all of these cases there has been a postoperative elevation of temperature. The pulse as a rule does not increase in rapidity. The patient complains of but little postoperative pain. It has become the writer's routine practice to use this preparation in all cases in which there is a possibility of postoperative adhesive formation.

1. **Epilepsy, with Special Reference to Treatment.**—Francis X. Dercum says that after we review the facts that have been hastily summarized, one fact stands forth with striking prominence, namely, that epilepsy is not a specific clinical entity. Under the caption of epilepsy are included many symptom groups which differ widely as to their origin and pathology. A specific treatment of epilepsy is obviously out of the question, and the first step must be an intensive study of each individual case. The first indication in the treatment is that the organism shall lead as physiological a life as is compatible with its structure. To attain this end, a life without physical or mental strain, close to nature, in camp or on the farm, should be adopted by the epileptic. This, indeed, is the principle applied in the various epileptic colonies. In addition, three points should be borne in mind: 1. The diet should be so modified that in this organism, already toxic, as little strain as possible be placed on the liver, the thyroid and other defensive glands. For this reason the red meats are to be partaken of sparingly. The carbohydrates also are to be diminished. To take the latter in large amount is to hamper the oxidation of the tissues, an oxidation which for the obvious reason of the autotoxicity of the patient should be maintained at as high a level as possible. In the diet, emphasis should be laid on the white meats, the succulent vegetables and milk; eggs also may be permitted. Stimulants of all kinds are, of course, to be excluded. 2. The various avenues of elimination should be kept freely open. If the diet does not of itself counteract the constipation frequently present, a moderate dose of a simple saline or laxative water may

be given daily. The patient should drink water freely between meals to promote the action of the kidneys, and should take a lukewarm sponge bath daily to promote the action of the skin. The bath should not be such as to promote an active reaction, but merely to favor elimination. 3. Resort to medicines must, of course, be had in many cases to influence or control the seizures. Experience teaches that chief reliance must be placed on the bromids. Regarding their efficient administration, however, one important point must be borne in mind, namely, the principle of sodium chloride withdrawal introduced by Richet and Toulouse. If table salt is withheld, the bromids instead of being eliminated are retained and are effective in much smaller dose. The writer has been in the habit for many years past of administering the bromids in the form of sodium bromide, at the same time instituting as rigid a withdrawal of the sodium chloride as possible. He says there can be no doubt that under these circumstances the sodium bromide takes the place, in a measure, of the sodium chloride in the tissues. If, in a case so treated, the sodium bromide be discontinued and sodium chloride resumed, the bromide is rapidly eliminated in the urine. In a given number of instances, the physiological level of the patient may be distinctly raised by the administration from time to time of small doses of thyroid extract; say from an eighth to a quarter of a grain three times daily, seldom more. Thyroid in small doses, long continued, stimulates the chain of glands of internal secretion, increases oxidation and promotes metabolism generally.

3. **The Transplantation of Ductless Glands, with Special Reference to Permanence and Function.**—O. T. Manley and David Marine say that in the course of their work during the past three years, they studied the transplantation of ovary, suprarenal (cortex and medulla), spleen, parathyroid, and thyroid of rabbits. Because the thyroid has several advantages such as accessibility, wide range of morphological changes, and its specific iodin reaction, the following summary is based for the most part on their experiments with the thyroid gland: Concerning autografts we have been able to confirm the conclusions of others that thyroid when transplanted shows all the evidence of growth, function, and permanence, and to the same degree, as does the non-transplanted thyroid. This work also shows that specific nerves, whether secretory or regulatory, are not necessary for the control of growth or of function in the case of the thyroid. Concerning the behavior of thyroid homograft, it seems established that both the host and the tissue used for the grafts modify their duration. These two factors may be quite independent, antagonistic to, or helpful to each other. In the case of the thyroid this reaction may be modified by iodine. Lastly, the future of tissue transplantation as a therapeutic means rests on a solution of the problem of the homograft, and it is also certain that whatever headway is made in overcoming the obstacles to homografting will to an equal degree be applicable to the solution of the tumor problem.

4. **Amino Acid Nitrogen in the Systemic Blood of Children in Health and Disease.**—C. J. V. Pettibone and F. W. Schlutz. (See MEDICAL RECORD, June 24, 1916, page 1156.)

6. **A New Shortening Technique.**—Roderic O'Connor tells of the development of the method, gives the technique in details and makes a report on 42 operations. He says the mechanical factors that operate against successful results in advancement are the constriction of tissues by sutures or ligatures, the tension on point of union by the operated muscle and its opponent, the anatomical formation of the tendons with their parallel fibers but loosely held together, the stretching of the operated muscle, causing paresis, and the retraction of the globe into the orbit. In the operation described the points essential to success are: A clear field of operation with the entire tendon in view, placing the catgut loop the proper distance from the insertion, and sliding the tendon loops into close contact and retention in that position by the ligature of fine catgut. Out of 42 operations in 35 cases there were but three absolute failures as follows: In one case, owing to gonococcus infection several days after operation; in another case on inferior rectus, owing to the use of too small a catgut, and thus being an error of judgment excusable when it is remembered that it was his first operation on that muscle and he had no previous experience to guide him; in the third case, owing also to too small a catgut. If this had been a case under cocaine the error of judgment could have been corrected at once. In future in such cases he said he would allow the patient to come out of the anesthetic to see if enough effect had been secured, and if not, remedy the failure at once.

8. **The Effect of Activity on the Histological Structure of Nerve Cells.**—R. A. Kocher says there is the utmost divergence of opinion as to the nature of the changes taking place in nerve cells following activity, and one who tries to correlate the findings of the different workers in this field is utterly confused. The chief findings relate to (a) size of cell body and nucleus, and (b) amount and distribution of chromatic material. In conclusion he states that there could be found no constant difference in the size of the nerve cells or nuclei resulting from activity. An apparent difference in size which appeared here and there on counting a small number of cells was shown on enlarging the series to be counterbalanced by a similar variation on the part of the controls. Hence it must be concluded that any difference in size of cells found was within the limits of normal variation. Furthermore, in no experiment did the histological structure of the nerve cell following activity, even to the point of exhaustion, show any constant deviation from that of the corresponding resting cells of the controls. Some very sweeping generalizations have been drawn from the conclusions of previous workers; namely, that fatigue, fear, shock, and exhaustion may lead to permanent damage and even disintegration of nerve cells. Crile's present theory of surgical shock and of certain aspects of exophthalmic goiter, based essentially on these assumptions, may be cited to show to what extremes these deductions have led.

2. **Prevention and Treatment of Cholera.**—S. M. Cox, in an address before a Medical Conference in Malta, says there is little hope of treating cholera successfully by a bactericidal serum, when it is fully developed. The best hope of combating the disease is through prophylactic inoculation. He has treated over 2000 cases since 1907 and has found that at the collapse stage of the disease a continuous intravenous saline infusion offers certain advantages. After the infusion of five pints a reaction rigor sets in. The continuance of the infusion up to eight or ten pints results in a dilution of the blood; elevation of blood pressure, with reestablishment of supressed renal flow; elimination of the endotoxins from the blood and later from the stools, thus obviating the onset of febrile reaction stage of cholera, the remainder of the illness being usually apyrexial. The essential features of the apparatus used, apart from the heat-regulating apparatus, can be easily improvised. The procedure and requirements for doing this are detailed.

3. **Cause and Nature of the Changes Which Occur in Muscle After Nerve Section.**—J. N. Langley reviews the theories to account for the fact that section of a nerve causes atrophic changes in the muscle it supplies. By experiments in electrical stimulation he has tested the theory that the maintenance of nutritive conditions of the muscle depends upon its contracting at intervals, so that when the normally occurring contractions are prevented by nerve section the nutritive condition of the muscle suffers, and it gradually loses weight and decreases in irritability. If this theory were true a certain degree of contraction brought about by electrical stimulation would keep the denervated muscles in a normal condition. The author points out that this does not occur in clinical practice. He relates his experiments on rabbits from which he concludes that the changes which take place after nerve sections are not due to absence of contraction, and the term "disuse atrophy" is a misnomer. It therefore becomes necessary to look for some other cause of the atrophic and degenerative changes. Professor Kato and the writer noticed that muscles from about the fourth day after section of their nerves are in a state of continuous fibrilation, *i.e.* the separate muscle fibers contract rhythmically, but with different rhythms; the muscles present a shimmering appearance when viewed by light reflected from their surface. The contractions cause no movements of the muscle as a whole and are easily overlooked. As each fiber contracts many times a minute the total expenditure in a day must be considerable. It is then reasonable to suppose that this continued activity of the muscle fibers must cause fatigue and that the atrophy of the muscle is due to too great rather than too little functional activity. The changes in reaction which occur in denervated muscle are, in fact, like those caused by fatigue.

4. **The Diagnosis of Cancer of the Stomach.**—James Alexander Lindsay presents an analysis of 40 cases of cancer of the stomach which have occurred in his practice at the Royal Victoria Hospital. A history of previous gastric ulcer was obtained in only five cases, or 12½ per cent. Only 4 patients gave a history of alcoholic excess. The symptoms which first attracted the patient's attention were as follows: Painful dyspepsia, 15 cases, or 37½ per cent.; vomiting and pyrosis, 9 cases, or 22½ per cent.; loss of weight, 6 cases, or 15 per cent.; progressive weakness and anemia, 4 cases, or 10 per cent.; hematemesis, 3 cases, or 7½ per cent.; anorexia, 2 cases, or 5 per cent.; melena, 1 case, or 2½ per cent. A tumor was detected in 15 cases in this series. Its value as a signal symptom the writer does not consider great. Enlargement of the liver was noted in 9 cases in this series. In discussing the early symptoms the author states that loss of appetite may be early and marked, and may be the first symptom to attract attention. Oftener it develops gradually. It is usually a prominent feature in established cases. The dyspepsia of gastric cancer is attended by discomfort and pain, sense of fullness in the epigastrium, nausea, sickness, eructations of offensive gases, and in most cases vomiting. These symptoms are at first related to the ingestion of food, but at a later stage they become more or less constant. The differentiation of gastric cancer from chronic gastritis, non-malignant gastric ulcer, non-malignant pyloric growth, pernicious anemia, and phthisis are discussed.

5. **On a Substitute for Peptone and a Standard Nutrient Medium for Bacteriological Purposes.**—Sidney W. Cole and H. Onslow have been conducting experiments for the purpose of finding a substitute for the peptones the supply of which has been cut off from Germany during the war. In the process of this work they have found a sharp criterion for a standard nutrient medium. If a medium containing a fermentable carbohydrate be sown with a specific organism a definite final hydrogen-ion concentration is reached. This is dependent to a remarkable degree upon the constitution of the fluid, a very slight change in which may cause a considerable variation in acidity. This effect is most clearly seen if more than one organism be employed. In fact, it was often noticed that the degrees of acidity produced by two organisms might actually be inverted. With these views and facts in mind the authors made experiments with various media containing an abundant supply of these amino-acids. The growth on such media of a large number of pathogenic organisms is so rapid compared with their growth on the recognized standard media that the method of preparing this media is presented in the hope that it will be found a cheap and effective substitute for peptone and nutrient broths. The authors also describe a simple method of standardizing the reaction of media, based on Walpole's principle of eliminating the color of the broth by use of a special tintometer. They state that the supply of free amino-acid is best obtained by the tryptic digestion of casein, and to secure uniform results a pancreatic extract is used, prepared by a method which follows a formula given by Mellanby and Woolley. The details of its preparation are presented.

7. **Intestinal Toxins and the Circulation.** — D. T. Barry has been following up the investigation of the action of excretory toxins on the neuromuscular mechanism of the heart and has tried to ascertain approximately the level at which the alimentary toxin begins to be formed. As in the previous experiments the toad's heart was perfused through the inferior vena cava, using the intestinal contents, which were mixed with Ringer's solution in a mortar, and the solution rapidly filtered with the aid of a water pump. Extracts were used from the upper, middle, and lower third of the small intestine. The effects on the blood pressure and heart beat of intravenous injections of the intes tinal contents of the animals themselves was also investigated. These experiments indicate that there is little doubt that substances having a deleterious action on the heart musculature and nerves are formed both in the small and large intestine, even under apparently normal circumstances. It is quite conceivable that such products, whether of bacterial or ferment action, may on occasion exist in excessive quantity and find access by absorption to the circulation; or that certain conditions may determine undue absorption when they exist in ordinary amounts. Peptone has a depressing effect on the blood pressure, but practically no peptone

is shown to exist in those regions of the gut where the toxicity is most marked. If the contents of the lower end of the ileum are acidified and boiled, then filtered, and to the filtrate alcohol or tannic acid is added, no appreciable precipitate is formed. The writer thinks it is reasonable to assume that prolonged absorption of even minute quantities of toxins would produce effects on the mammalian heart similar to those immediately produced in the toad's heart by comparatively strong concentration; that many conditions of irregularity and block in the human heart in Stokes-Adams and other affections seem to fall into line with the action of these substances, and that a systematic course of treatment of the alimentary canal antiseptically and otherwise should be of the greatest service in some of these cases.

British Medical Journal.

July 1, 1916.

1. Notes on Military Orthopedics. V. Transplantation of Bone, and Some Uses of the Bone Graft. Robert Jones.
2. On the Life-History of Ascaris Lumbricoides. F. H. Stewart.
3. Disinfection of the Nasopharynx of Meningococcus Carriers by Means of Air Saturated with a Solution of Disinfectant. M. H. Gordon.
4. Paralysis of the Intestine After Resection for Gunshot Injuries. Owen Richards and John Fraser, with Note by Cuthbert Wallace.
5. Postoperative Paralytic Ileus. H. T. Hicks.
6. The Treatment of Backward Displacements of the Uterus. (Concluded.) Frederick J. McCann.

1. Transplantation of Bone, and Some Uses of the Bone Graft.—Robert Jones, in concluding an account of his experience in the grafting of bone says that whatever particular theory of osteogenesis may be the true one, he has found the following points valuable in practice: The area of the graft must be kept scrupulously aseptic, and free from unnecessary blood clot. Adequate blood supply is necessary to the growth of the graft. The graft must be placed in close apposition to raw surfaces of the bone with which it is to unite. The whole region must be kept fixed for a long period for undisturbed organization to take place. The bone graft should be autogenous, and it is better that it should include both periosteum and medulla wherever this is possible, for both these aspects of the bone afford facilities for the growth of new blood vessels. Surgeons should have patience, for union is often delayed, and hasty conclusions that union is not going to take place, and consequent relaxation of strict fixation of the part, may convert a case of delayed union into one of non-union. After any procedure of bonegrafting it is essential to fix the limb absolutely to let new vessels grow undisturbed by chance movements, for the idea of the operation is that all the transplanted bits of bone shall become vascularized. As a general rule, the limb should be kept fixed and undisturbed for at least twice the time necessary for union of the same bone in an ordinary simple fracture since there is no definite time within which a fracture will unite. It is difficult to formulate an exact rule as to when a bone grafting operation should be performed, for the danger of re-crudescent sepsis seems never to be absent. It is the essayist's habit to wait for at least six months after a sinus is closed, during which time and for a variable period afterwards efforts should be made to improve the general nutrition of the limb. Early operation is to be discouraged from every point of view, and failure to observe this fact has resulted in many a tragedy.

2. On the Life History of Ascaris Lumbricoides.—F. H. Stewart describes his experiments on pigs and rats which apparently show that, contrary to the generally accepted theory, the life history of *Ascaris lumbricoides* presents an alternation of hosts. Eggs develop mature embryos in the outer world in a damp atmosphere, preferably at a temperature of 25° to 30° C. When ripe eggs reach the alimentary canal of the rat or mouse they hatch. The larvæ liberated enter the bodies of their host, a few only escaping in the feces. Between four and six days after infection they are found in the blood vessels of the lungs, liver, and spleen. The host is seriously ill with symptoms of pneumonia. On the sixth day they have passed from the blood vessels into the air vesicles of the lung causing hemorrhage into them. On the tenth day they are found only in the vesicles of the lung and in the bronchi. If the disease does not prove fatal the host recovers on the eleventh or twelfth day. On the sixteenth day the host is free from the parasite. It is obvious that the transfer of the parasite from the bronchi of the rat or mouse to the intestine of man and of the pig could be readily effected. The writer concludes that the further course of the life history of this parasite requires additional study for its elucidation.

3. Disinfection of the Nasopharynx of Meningococcus Carriers.—M. H. Gordon has made observations to ascertain whether the air of a room when saturated with water vapor containing chloramine exerts bactericidal properties, and if so to what extent such air can be tolerated by human beings. He describes the procedure which he has followed in a number of experiments which he finds warrant the following conclusions: 1. The air of an ordinary room, when brought to the point of saturation by means of a steam spray containing 2 per cent. of chloramine, acquires pronounced bactericidal properties for *Staphylococcus epidermidis*. 2. Such air can be tolerated by human beings for a period varying from six to twenty minutes without marked discomfort and without harm. 3. When inhaled through the nose, this air succeeds temporarily in destroying the meningococcus in the nasopharynx of carriers. Its sphere of usefulness in this and other respects is being more closely investigated. In view of the simplicity and convenience of the method and its obvious suitability for the purpose of dealing with a large number of carriers at a time, the above results are encouraging.

4. Paralysis of the Intestine After Resection for Gunshot Injuries.—Owen Richards and John Fraser observe that this complication seems to occur only in the small intestine, the segments of the intestine above the union becoming distended, while the segment below remains contracted. The writers report several cases from which they conclude that in cases operated on is probably mainly due to some interference with the within a short time after the receipt of the injury this nervous mechanism, caused by the injury itself and the resultant shock, and increased by other causes—for example, local peritonitis. In cases operated on after a considerable interval, a further cause is that continued obstruction, and consequent septic absorption, render the bowel above incapable of rapid recovery. A case in which this complication has occurred may possibly be saved by subsequent short-circuiting of the affected coil. Cuthbert Wallace comments on two of the cases reported in which resection and circular enterorrhaphy were performed, one in the lower ileum and one in the upper jejunum. A short circuit operation was performed in both to relieve a distention which was limited to the small gut above the line of the circular enterorrhaphy. The cause of the obstruction was a paralysis of the bowel below the site of the operation, which was not due to septic peritonitis but to some acquired defect. It would be advisable in these cases to make the anastomotic opening at a considerable distance from the lesion, or to short circuit into the transverse colon, as suggested by Sampson and Handley.

Book Reviews.

THE INTERNATIONAL MEDICAL ANNUAL. A Year Book of Treatment and Practitioner's Index. 1916. Thirty-fourth Year. Price, $4 net. New York: William Wood and Company.

THE International Medical Annual has had a long and honorable history as a publication of service to all English-speaking practitioners. Among its contributors this year are two New York men, Lewis A. Conner, who has written on Pulmonary Diseases, and J. Ramsay Hunt, who presents the Diseases of the Nervous System. It is but natural and right that a very important portion of this issue should be given over to the consideration of naval and military surgery, and this has been done very thoroughly. It should not be thought, however, that any of the other branches of medicine have on this account been neglected. This number is as interesting and instructive and as complete as any of its predecessors and will serve admirably to maintain the position of the series in medical literature. No other publication quite fills the position of the Annual and we are sure that no other will ever succeed in doing so.

A TREATISE ON THE PRINCIPLES AND PRACTICE OF MEDICINE. By ARTHUR R. EDWARDS, M.D., Professor of the Principles and Practice of Medicine and Clinical Medicine and Dean of the Northwestern University Medical School, Chicago. Third edition, thoroughly revised. Price, $6. Philadelphia and New York: Lea and Febiger, 1916.

WHILE one-volume treatises on the practice of medicine must inevitably have many faults they also may possess definite advantages, and that there will always be a demand for them is certain. The present example of the class is distinctly meritorious, and that it has found favor with many readers is shown by the fact that it is in its third edition. Features of especial interest are the very many diagnostic tables, in which conditions sometimes difficult to differentiate are contrasted, and the sections on treatment which are much more satisfactory than is usually the case in similar works. The text is modern in its presentation of most subjects, and though some readers may be disappointed at not finding such topics as the significance of the nitrogen partition in the blood, the fasting treatment of diabetes, or the present conceptions of acidosis fully discussed, such matter is hardly to be expected in a book of this scope. It is a pleasure to commend it as most excellent of its kind.

INTERNATIONAL CLINICS. A Quarterly of Illustrated Clinical Lectures and Especially Prepared Original Articles on Treatment, Medicine, Surgery, etc. Edited by H. R. M. LANDIS, M.D. Vol. I, Twenty-sixth series, 1916. Price, $2. Philadelphia and London: J. B. Lippincott Company.

THIS number of the "Clinics" contains seventeen articles on Treatment, Medicine, Neurology, Public Health, Pathology, Gynecology and Surgery. In an article on chorea by E. E. and W. H. Mayer the treatment by the intravenous administration of phenol is recommended and seven successful cases are reported. This treatment is used apparently because of the authors' belief that chorea is an infection and that the phenol acts as a disinfectant. Whether there is any analogy between this and the well-known Baccelli treatment of tetanus cannot be said, but it is to be hoped that other observers will be able to confirm their results. They have adopted what is apparently an unnecessarily scornful attitude toward the bacteriological work which has been done on the streptococcus group of infections. Satterthwaite's article on Drug Therapy in Cardiovascular Diseases embodies many ideas in regard to digitalis which are at variance with the views held generally to-day. There are several other articles of interest which make this number conspicuous. The "Clinics" starts out well under its new editor and there is every indication that its present success will follow it in the future.

A TEXTBOOK OF NERVOUS DISEASES for Students and Practising Physicians, in Thirty Lectures. By ROBERT BING, Dozent for Neurology at the University of Basel. Only Authorized Translation by CHARLES L. ALLEN, M.D., Los Angeles, Cal.; with 111 illustrations in the text. Price, $5. New York: Rebman Company.

NERVOUS diseases for many reasons bulk large nowadays. The manner in which we live has the tendency not only to keep our nerves at a high tension, but to find out the weak spots in the armor of our nervous system. Moreover, neurology has now been brought to a more or less scientific basis and no medical student's education is considered complete unless he knows something of this branch of medical knowledge. The great teachers of neurology have been and are inhabitants of Continental Europe and among these Robert Bing, whose book is being noticed, is by no means the least distinguished. The subject matter in this work is presented in the form of lectures, which have been systematically arranged for publication in book form. In the arrangement of the material, the customary topographical and pathologico-anatomical classification has been subordinated almost entirely to the etiological and pathologico-physiological. This was done in order to condense the work to a suitable size. The author states in his preface that he has refrained from forcing to the front the views of any particular school, but has endeavored rather to exercise a certain eclecticism which is justly considered as the scientific signature of Switzerland, in which the German and the Latin manner of thought and investigation blend and reinforce one another in harmonious fashion. This work may be regarded as a thoroughly useful, practical, up-to-date book, and as such of great value to students and practitioners.

PAINLESS CHILDBIRTH, EUTOCIA AND NITROUS OXID-OXYGEN ANALGESIA. By CARL HENRY DAVIS, A.B., M.D. Associate in Obstetrics and Gynecology, Rush Medical College in affiliation with the University of Chicago; Assistant Attending Obstetrician and Gynecologist to the Presbyterian Hospital, Chicago. Price, $1. Chicago: Forbes & Co., 1916.

THE recent lay agitation in regard to Twilight Sleep has called forth numerous articles on analgesia in obstetric practice. The first articles dealt with the value or difficulties of scopolamine and morphine administration. Later, reports from several hospitals appeared, where nitrous oxide and oxygen had been used during labor with excellent results. Dr. Davis' book discusses these two methods of obtaining painless childbirth. After reviewing the introduction of anesthetics into obstetrics, he takes up the pharmacology and toxicology of the drugs whose use he afterward considers—scopolamine and morphine, nitrous oxide and oxygen. The advantages of nitrous oxide and oxygen analgesia are given in a report of results in 104 cases at the Presbyterian Hospital, Chicago. Dr. Davis found that labor was shorter, tears were fewer, the babies lost less weight, and the women were able to leave the hospital earlier. Cumbersome apparatus will largely limit the use of this method in private practice, except among the wealthy, but this will be only an added argument for hospital care of obstetric cases.

INSTINCT AND INTELLIGENCE. By N. C. MACNAMARA, F.R.C.S. Price, $2.00. London: Henry Frowde, Oxford University Press. Hodder & Stoughton. New York: Oxford University Press, American Branch, 1915.

MACNAMARA in his preface says, "In the following pages we have endeavored to give an outline of the evidence, and the reasons upon which we rely to prove that the instinctive behavior of human beings depends on work performed by definite parts of the brain; consequently, education has not only to deal with the training of something immaterial which we call mind or consciousness, but has first and foremost to deal with the proper development of the nervous substance of that part of the brain the orderly working of which is essential for the occurrence of instinctive and intellectual phenomena." He traces the development of the nervous system from atoms, molecules, and energy in amebas, insects, amphioxus, apes, idiots and finally intellectual beings. He shows how instinctive response to stimuli becomes more elaborate with higher forms, and how with the development of the cerebrum, intelligence, defending an association of ideas, somes in. Then, he says, "If the evidence referred to in this and the preceding chapters is trustworthy, and the hypotheses founded on it reasonable, it follows that any effort made to develop the moral and intellectual capacities of young people should be directed towards the efficient training and nurture of the nervous substance upon which this manifestation of these faculties depend; to be more precise, our efforts should be directed towards developing the nervous instinctive basic substance of the basal ganglia, and of the association areas of the neopallium."

Society Reports.

AMERICAN NEUROLOGICAL ASSOCIATION.

Forty-second Annual Meeting, Held at Washington, D. C., May 8-10, 1916.

THE PRESIDENT, DR. LEWELLYS F. BARKER OF BALTIMORE, IN THE CHAIR.

(*Concluded from page 216*)

Obstetrical Paralysis.—Drs. JOHN JENKS THOMAS and JAMES WARREN SEVER of Boston prepared this paper, which was presented by Dr. Thomas, who said that there was no evidence from their experimental work or clinical observation to support the theories of Lange and T. Turner Thomas that the primary cause of obstetrical paralysis lay in an injury of the capsule of the shoulder joint or a dislocation, with secondary damage to the nerve trunks. This theory got no support from experimental work, and in addition did not account for the distribution of the paresis of muscles generally seen, such as the spinati, supplied by the suprascapular nerves, nor the frequent involvement of the sympathetic fibers going to the pupil and eyelid, often seen in cases of paralysis of the whole arm, and of the lower arm group. The partial dislocation of the head of the humerus backward, the bending down of the tip of the acromion, and the forward dislocation of the upper end of the radius were all secondary changes, due to the formation of contractures in the stronger or unaffected muscles. Dislocations of the shoulder, separation of the epiphyseal end of the humerus, or fractures of its shaft, like fractures of the clavicle, were infrequent accidents, and, while they might be unaccompanied by an injury of the plexus, more frequently they were complicating injuries which rarely caused permanent difficulties. The treatment to be effective must be adapted to the conditions in the individual case. Treatment by massage of the paralyzed muscles and development of them as they recover through educational exercises were necessary in all cases where the plexus had been injured to more than a very slight extent. Resection of the plexus and transplantation of torn nerve roots of the plexus were to be reserved for cases which did not show evidence of recovery of function in definite groups of muscles within a reasonable time, generally not less than six months, though frequently this time needed to be extended to a year, a year and a half, or occasionally even longer. The late complicating deformities about the shoulder and elbow joints should be treated on orthopedic principles. The writers presented a new operation for this deformity at the shoulder joint by division of the tendon of the subscapular muscles outside the joint. These cases needed careful after-treatment by passive movement massage and educational exercises to bring about free and natural movement in the joints and use of the extremity.

Dr. CHARLES K. MILLS of Philadelphia said that he had seen many cases of obstetrical paralysis and had also published a small amount of matter with regard to traumatic brachial palsy. One thing seemed to him to have been omitted entirely, or else he did not listen with sufficient attention. He believed that these obstetrical palsies were due in a large percentage of the cases not to the direct lesion of the brachial plexus or of the shoulder, although these were present, but that they were due to an avulsion of the nerve roots of the plexus. It seemed to him this should be understood. He worked sometimes with T. Turner Thomas, and they had had this matter up in connection with one of the cases of injury to the shoulder and plexus, with regard to which he contributed a paper to one of the journals. However, it did not take away from the value of these observations and these experimentations for relief. Traction on the plexus, which frayed the nerves, always occurred; the avulsion of the nerve roots or a certain part of the nerve roots of the plexus, and therefore a total and permanent destruction which could never be very fully or largely relieved except by adaptation or compensatory operation.

Dr. TAYLOR of Boston said that there were two or three points he would like to make in regard to brachial palsy injuries; in the first place, in regard to the etiology. In a paper which he had presented to this society in Baltimore it had been stated that there were at least twenty experimental productions of this lesion on new-born babes who had died a few hours after birth. In every one extraspinal. In sixty operative cases, in only 10 per cent. was it fair to presume that there had been an intraspinal lesion. In a case which had not been published he was called upon to deliver a woman with a badly deformed pelvis. It was necessary to do version, in which the extraction was a breech extraction, and, feeling that this type of lesion was exceedingly apt to occur, he put most of the traction on the lower extremities of the child until they were damaged so that he did not dare continue; then the pressure was exerted over the shoulder and a lesion of the brachial plexus occurred where he had stated before the delivery of the child's head that such a lesion would occur. After delivery he found it had double hemorrhage from both hemispheres. If one explored a child in the early weeks of its career and one did not find damage to the plexus requiring surgical repair, he had done nothing more than make an incision 2 inches in the skin, subcutaneous fat, and fascia. That gave one an opportunity to observe the brachial plexus. On the other hand, if one found a serious surgical damage to that plexus, then he could do the repair at the time most favorable to the child and the risk one had run was justified by the improvement that took place.

Dr. JOHN JENKS THOMAS of Boston said that he thought Dr. Taylor had given us fully what Dr. Mills had alluded to. We know that the lesion in these cases was not a constant one. It varied in severity and in the situation of the injury. Occasionally avulsion of nerve roots was seen. Some of their cases had shown separation between the nerves of the plexus. He could not agree with Dr. Taylor on the advisabilty of early exploratory operation in all cases. Certainly he thought that should never be done in cases where at the time, soon after birth, we found the injury limited to the upper arm group of muscles. These cases practically all showed partial recovery after operation. The question was somewhat different when we came to total arm paralysis. He thought their work had given them a clue as to why this was so. In the upper arm paralysis, although the nerves were stretched, there was fraying out of the fibers and hemorrhage within the sheath; there was no complete separation or tear of the plexus. The only complete injury we found then was the tearing off of the suprascapular nerve. To suture the suprascapular nerve, which was very small in the infant, he thought was practically impossible. His plea was that we should make our treatments suit the individual case.

Further Contribution to the Treatment of Syphilis of the Nervous System.—Drs. B. SACHS, I. STRAUSS, and D. J. KALISKI of New York City prepared this paper, which was read by Dr. Sachs. Two years ago they reported 120 cases; to-day they reported 100 other cases, twenty treated by the intraspinous method, the others by the intravenous method. Omitting all the unnecessary detail, they were forced to conclude that the intravenous method was the one that they preferred by all odds to the intraspinous method, for the reason that the intravenous method had given absolutely satisfactory results and by the intraspinous method they had not obtained a single result that they could not have obtained by the intravenous method. The intraspinous method was attended by all sorts of disagreeable complications and discomfort of the patient, which increased the risk enormously. They had evolved a system of intensified intravenous treatment which was even more intensive than the form of treatment originally suggested by Dreifus. In some of the cases intravenous treatment was given by small doses daily, sometimes for five or ten days. Then a period of rest of four or five days, or a week; then followed a series of intensive mercurial treatments. The intravenous treatment of salvarsan should be observed most carefully, with special reference to the effect on the kidneys.

Dr. JOSEPH COLLINS of New York said that he was now in the position of holding no brief for the Wassermann reaction *per se*. He had no faith in it compared with other methods of diagnosis of syphilis. The Wassermann reaction meant nothing more than that we should be suspicious of syphilis. If a person came in to him and had only a plus Wassermann, he would say, "You marry." That was a different state of mind from two years ago. He believed that the Wassermann test has been far overrated in its value to the clinician. A few months ago, when this matter had been under discussion before the New York Academy of Medicine and he had made the statement that he was quite unwilling to pin much faith to the Wassermann reaction unless he found some changes of the biological reactions, all the speakers had said in closing that they were sure he was mistaken. He agreed with Dr. Sachs that the intravenous method of administering salvarsan or

arsenobenzol was preferable to the intraspinal. During the last two years Dr. Craig and himself had devoted themselves to the use of salvarsan intraspinously. They were convinced this had no advantage over the intravenous method.

Dr. C. EUGENE RIGGS of St. Paul, Minn., said that during the last two years he had closely watched the effects of the intravenous as compared with the intraspinous method, and his experience had not been in harmony with that of Dr. Sachs. In between 400 and 500 cases he had had no unpleasant experience with the intraspinous method aside from one case of cerebrospinal meningitis, which had made a good recovery.

Dr. E. E. SOUTHARD of Boston said that in respect to Dr. Collins' remarks in reference to marriage he would say that if anyone came to him with a doubtful Wassermann reaction he should regard that his desire to marry was a psychopathic one, and he should at once counsel lumbar puncture. He would rely upon the results then. He would have repeated Wassermann tests. He regarded it as a medical crime for a person with a positive Wassermann and any mental symptoms not to receive a lumbar puncture.

Dr. B. SACHS of New York said that in reference to what Dr. Southard had said, he thought he was in general agreement with him, although he did not think every candidate for marriage should be penalized by a lumbar puncture. In order not to be misunderstood, he would say that in all of their work they had endeavored to obtain negative reactions as regards the cerebrospinal fluid. In regard to the Wassermann reaction of the blood, they allowed that one condition to persist without insisting that the antisyphilitic treatment must be coninued to the extreme until a change in the Wassermann reaction of the blood was effected. As regarded the intraspinous form of therapy, they had a right to speak authoritatively so that the general practitioner should not be made to feel that here was the great solution to the question of antisyphilitic treatment. The attention of the general practitioner should be directed to the far greater dangers of the intraspinous as compared to the intravenous method, and the fact that it accomplished nothing that we could not accomplish by the far safer intravenous method.

Dr. I. STRAUSS of New York said that to show that in the last two years there had been a change in opinion and that we were not altogether wrong in our stand he would call attention to the fact that the very individuals who used the salvarsanized serum had turned to what they called the method of salvarsan plus salvarsanized serum. In other words, finding the salvarsanized serum contained no antibody, they had added this amount of salvarsan, which was practically 1 mgm., to their fluid to obtain their results. Regarding the dangers of this intraspinous method, there were two cases in his experience which showed that this method was not so harmless as generally portrayed. Unfortunately, he thought medical men were a little careless in reporting the sad results of therapy.

Types of Neurological Cases Seen at a Base Hospital.—Dr. JOHN JENKS THOMAS of Boston read this paper, saying that injuries of the peripheral nerves were frequent, but many that appeared total were, on careful examination, found to be partial. Immediate interference except for the suture of obviously severed nerves and to prevent their retraction was seldom advisable, as all wounds were septic. When an operation was necessary it should be done after the wound was healed, and followed the usual lines of those for other injuries of peripheral nerves. The spinal cord might be injured directly by fragments of bone or muscle, but not infrequently also indirectly through concussion, producing hematomychia. At first almost all these cases showed complete sensory and motor paralysis, and the true extent of the damage could be determined only after a time. Injuries of the brain from bullet wounds were fairly frequent at base hospitals, and many of these did surprisingly well. Primary operation except for checking hemorrhage should be avoided. In a good many instances with bullet wounds they found tangental wounds because of the high velocity, but in these, even though they found no extensive fragmentation of the inner table of the skull, the bullet very frequently lacerated the dura as it channeled the bone. Therefore, all of these bullet wounds of the head which were so located that an injury of the brain might have occurred should be explored. Functional disturbances of the nervous system were seen quite frequently at the base hospitals. Curiously enough, these functional cases seemed to develop most often, at least during the first few weeks after being incapacitated, in the men who had not been wounded, being mostly in those who had been thrown down by the concussion produced by the bursting of high explosive shells of large caliber or who had been buried in the dirt, as when a trench or dugout had been blown in by such shells.

Syringoencephalomyelia; The Function of the Pyramidal Tract.—Dr. WILLIAM G. SPILLER of Philadelphia read this paper, in which he stated that it had been asserted that syringomyelia did not extend above the lower part of the pons and no term was employed in medical literature to indicate the implication of the brain in the syringomyelic process except syringobulbia, a term applicable only to the lower part of the brain. He showed in 1906 that the syringomyelic process might extend upward through the brain into the uppermost part of the internal capsule and almost into the lateral ventricle. He now proposed the terms syringoencephalia and syringoencephalomyelia for those conditions confined to the brain or implicating the brain as well as the spinal cord and of the same character as syringomyelia. Syringomyelia was a term applied to cavity formation in the spinal cord. The methods in which these cavities were formed vary. A common way was by defective closing in of the posterior columns, leaving a space which later enlarged. A similar defective closing in might occur in the brain. The aqueduct of Sylvius at one period of embryonic life was relatively large. In 1902 he reported a case of hydrocephalus caused by almost complete obliteration of the aqueduct by excessive closing in, and in this report he mentioned that the closure of the aqueduct resembled in the changes of tissue produced by it the condition often seen in the region of the central canal of the spinal cord, leaving nests of ependymal cells about it. He had now studied the aqueduct in microscopical sections from thirty-eight cases taken at random, and had found that the character of this opening varied greatly. It might have a long, narrow slit at its lower part lined by ependymal cells, and frequently had nests of ependymal cells about it. Possibly from these, as in the cord, tumors might have their origin later in life. He had recently studied a case in which the fissure existing in the embryo between the optic thalamus and the corpus striatum had failed to close in entirely to form the opto-striate notch and had left a fissure extending from the lateral ventricle into the brain, destroying the anterior half of the posterior limb of the internal capsule. This fissure was surrounded by thickened neuroglia and some nests of ependymal cells. The upper extremity of the opposite side had been moved freely during life, except that isolated movements of the fingrs had been impossible but no paralysis of the face had been detected, and yet the fibers supposed to furnish motor power to the upper extremity and face had been destroyed.

A Consideration of Some Selected Problems in a Year's Neuro-Surgical Service.—Dr. E. SACHS and Dr. SIDNEY I. SCHWAB of St. Louis prepared this paper, which was read by Dr. Sachs, who said that it was important to study neuro-surgical cases from two points of view, the neurological, which placed its emphasis on the production of symptoms in relation to a definitely placed lesion, and the surgical, which emphasized the question of the adaptability of a given lesion to surgical procedure. It was this shifting of emphasis at the hands of two differently trained observers which they believed would eventually satisfy the broadest demand of neuro-surgical cases. Each case was therefore studied independently by the neurologist and surgeon; the resulting data were gathered and discussed before it finally became either a strictly surgical problem or was discarded into the neurological class with no surgical outlook. Among the many problems that had arisen during the past year the following seven were selected for presentation and comment: 1. The reliability of the Bárány observations as tested on stimulation of the cerebellum in a conscious patient. 2. Significance of albuminuria in intracranial pressure. 3. Multiple lesions. 4. The place of lumbar puncture in intracranial pressure. 5. Pseudo-optic neuritis. 6. Tumors of the Gasserian ganglion in sinus conditions. 7. Disappearance of cord tumor symptoms after lumbar puncture.

Acroparesthesia.—Dr. JAMES J. PUTNAM of Boston read this paper, stating that the object of his paper was to seek a more adequate explanation of the nature and pathogenesis of the affection which Schultze had denominated acroparesthesia (recurrent numbness of the hands, etc.), the first thorough description of which had been given by the speaker in 1880 on the basis of the

analysis of thirty cases. He called attention particularly to the following points: 1. The tendency of the numbness to recur toward the latter part of the night and at first to be present only then. 2. The slight changes of coloring or consistence of the fingers. 3. The frequent changes of sensibility during the attacks. 4. The presence (as a predisposing cause?) of other neurotic tendencies. 5. The relation of the symptoms to the use of the hands, or their position, or to slight stimulation of the skin with hot or cold water, and in other ways. The best view to take of such a neurosis as this, and perhaps of all specific neuroses, was (1) that they pointed to a failure of the coordinated adjustments of the nervous system (relation to the neurotic temperament as a whole, etc.); (2) that they pointed to an attempt on the part of the organism to assert itself through some new dynamic and quasi-coordinatory effort as if seeking for some new equilibrium. But the new coordinatory equilibrium thus established was always a relatively poor one (substitution of vascular cramp for coordinated contraction and dilatation, etc.). The aim of the treatment should be, first, to restore the tone of the nervous system; second, to eliminate emotional complexion at variance with health; third, to remove accessory causes, such as toxemias (note the arthritic tendencies and digestive troubles present in many cases); fourth, to remove specific excitations, such as exposure of the hands to hot and cold water; fifth, to adopt means calculated to encourage adequate vascular reflexes (exercises of specific sorts). Quinine is often useful, especially for short periods and in large doses, perhaps acting as a vascular stimulant. Local heat and electricity also had a place, and the same might be said of occupational training of the patient.

Wednesday, May 10—Third Day.

Intramedullary Tumor of Cervical Cord. Probable Diagnosis. Removal in Two-Stage Operation; Gradual Improvement.—Drs. F. X. DERCUM and J. CHALMERS DACOSTA of Philadelphia prepared this paper in which they stated that they placed on record a case which had to do especially with the recognition and interpretation of pain of spinal origin. The significance of such pain was frequently overlooked. At times it was incorrectly ascribed to a visceral origin and had led to futile abdominal and other operations. The case was interesting because of the relatively rapid and extensive development of symptoms, suggesting a myelitis rather than a local lesion, because of the serological findings and finally because of the diagnosis of tumor and its successful localization and removal. The first symptoms of illness appeared in the latter part of October, 1913, namely, some vague pain or numbness in the left shoulder which did not hurt when moved or handled. Numbness gradually made its appearance in the left arm and later there was distinct weakness of the left arm. When the patient coughed or jarred himself, he had a sensation as of a "thrill going through his body." Soon numbness, weakness and pain appeared in the right arm. About a month later there was weakness in both legs and in the bladder. Walking became difficult and soon there was loss of sensation and paralysis in both legs. When admitted January 27, 1916, the patient was completely paraplegic and there was absolute loss of sensation of all forms as far as the level of the second rib. A slight plus patellar reflex was elicited upon both sides. No ankle clonus, but Babinski upon both sides. Marked general wasting of the hands, forearms, arms and shoulders, as well as of the trunk and of the lower extremities was present. The lumbricales, both the thenar and hypothenar eminences, and to a smaller extent the interossei were wasted in both hands. The pupils were equal, average in size and reacted to light. The Wassermann reaction was negative. On February 21, 1916, an exploratory operation was undertaken. Incision over the fourth, fifth, sixth, seventh cervical and first dorsal vertebræ and the processes and laminæ of the seventh cervical and first dorsal vertebræ removed. Immediate on opening the dura a dark, bluish-red mass began to extrude. It was evident that dissection would damage the cord and it was decided to follow Elsberg's plan of allowing the tumor to extrude. The patient reacted well from the operation and was comfortable. After five days the wound was reopened and the cord was again exposed. The edges of the incision had become considerably separated, the tumor had extruded in part, and it was now gently coaxed or teased from its bed in the cord with the aid of small pledgets of gauze. The tumor was exceedingly friable and soft and came away only in small fragments. The subsequent surgical course was without incident. Within twenty-four hours after the operation, the patient became cognizant when the left leg or foot were touched. He felt the touch as something hot or burning but he could not localize the impression save to say that it was the left limb which was touched. Within a few days the hypesthesia of the hands and arms grew markedly less and soon disappeared. This was followed by a rapid gain in power over the movements of the fingers, hands, wrists, forearms and indeed of the upper extremities generally. The improvement in the right upper extremity was somewhat more rapid than in the left. Twelve days after operation the patient was able to distinctly abduct the left thigh. Once or twice slight movements were noticed in the toes. Patient was able to flex and abduct the thighs, slightly, but the improvement in this respect had not kept pace with the improvement in sensation. When examined on April 27, 1916, his improvement as regards the sensory findings were less manifest than at the previous examination. In other respects the improvement had continued, though it had been slow.

The Rising Tide of Disabilities Following Trauma and Their Relation to Our Compensation Laws.—Dr. B. SACHS of New York read this paper, saying that in ten cases there was only one case in which he could say that there was a permanent disability following injury. That was a distinct brachial plexus neuritis which had not been recognized. Thus far he had not seen anything in this country comparable to the traumatic neuritis, as it had been established by Oppenheim many years ago. In the main, we as neurologists, should insist that the evidence should point to organic changes of the nervous system, central or peripheral, and that we should limit so far as possible the purely psychic element. Much more important than establishing the fact that there was or was not an organic change in the nervous system is the ruling out of organic nervous symptoms. A man who had a distinct spondylitis as the result of trauma a year before added to his regular symptoms any number of disabilities which could not possibly fit into the general conception of a spondylitis or traumatic myelitis in association with spondylitis. Simulation and malingering were very infrequent. In this country the attempt at simulation is not made as in Europe. There was a peculiar mental attitude in all these cases and the fear of having the earning capacity limited by the accident became a perfect obsession with the individual. Dr. Sachs had given the opinion that that mental attitude was to be considered as a disability following injury. He urged that the profession give due allowance to the mental attitude of the person who has been injured. The workman should be given the benefit of every doubt. Do not exaggerate. Rely upon the basis of the symptoms known to be connected with both the organic and the peripheral nervous system.

Dr. SMITH ELY JELLIFFE of New York City said that he was in very thorough sympathy with Dr. Sachs' remarks relative to the compensation material that is being thrust upon us. He thought that we could get a great deal of light upon the subject of malingering if we made tests upon the autonomic and sympathetic systems. They were very definite tests for definite organic conditions.

Dr. HUGH T. PATRICK of Chicago ventured to make a very unscientific but, he believed, practical suggestion. He believed that these groups creep over into each other. He was sure we all had had the experience of being unable to place a given case in a given group, and we had been driven to trying various remedial procedures and agents in the hope that we might cure or relieve the patient. Some of these patients were very promptly and, he believed, progressively relieved by a very simple procedure, the suggestion of which he got from Dr. Moyer, which was elastic constriction. The application of the rubber tubing or elastic rubber bandage about the extremity two or three times a day for two or three minutes would absolutely and completely relieve some of these cases in a very short time.

Dr. CHARLES L. DANA of New York City said that he presumed there was a psychogenic side, although he had never seen it. Aside from that group there was a large number due to the causes stated. One rather unusual case he had seen recently in which he thought he had discovered a cause not mentioned. He had had *x*-ray pictures made of the arms, and had found a very distinct evidence of thickening of the arteries of the

more affected arm. One arm was more paresthetic than the other. The history of the case, the character of the symptoms all indicate that it was a paresthesia due to vascular involvement. He thought the vasomotor system and the vascular system were behind the majority of the ordinary cases. There was one other group of cases which he thought ought to be watched very carefully, that was the kind of acroparesthesia with the beginning of combined sclerosis, associated with anemia.

Diffuse Endothelioma Enveloping Spinal Cord in its Entire Length.—Drs. PETER BASSOE of Chicago and C. L. SHIELDS of Salt Lake City prepared this paper, which was read by Dr. Bassoe, who said that the patient, a girl of sixteen years, had been taken with headache, vomiting and dizziness eight months before death. Later, failing vision, two weeks of strabismus, and finally complete blindness. Hearing also had been lost. The optic disks showed secondary atrophy, and the tendon reflexes were lost. The spinal fluid showed lymphocytosis and increased albumin. There had been convulsive seizures during the last two weeks before death. The necropsy revealed the unusual condition of a diffuse grayish-white thickening of the pia along the entire cord, most marked posteriorly. Histologically, this tumor proved to be of connective tissue.

Dr. HARVEY CUSHING of Boston said that he thought that in a series of about 100 cases of certified tumors that had been called endothelioma, there had been many examples of endotheliomatous effects. Many of these endotheliomas had heretofore been called sarcomas, and whether this tumor of Dr. Bassoe's should be called sarcoma he did not know. It was his feeling that these tumors were not dural tumors. He thought they were really arachnoid tumors and that they originated from the endothelial cells which covered the arachnoid tufts. He surmised that, if this original tumor was an endothelioma, this meant a sarcomatous degeneration in the tumor with invasion of the cerebrospinal space.

Dr. BASSOE said that in this case the dura had not been involved anywhere. As to the sarcoma and endothelioma question, that was a very long question. He would simply say if he were shown a slide with cerebellum without being familiar with the history of the case, that it was a fibrosarcoma, and a slide from any other part of the pia would pass for a round-cell sarcoma.

Preliminary Report on the Use of the Abderhalden Reaction in Mental Diseases.—Drs. HENRY A. COTTON of Trenton, N. J.; E. P. CORSON WHITE of Philadelphia, and W. W. STEVENSON of Trenton, N. J., prepared this paper which was read by Dr. Cotton, who said that, since Fauser in 1912, with the assistance of Abderhalden, had begun to apply the principle of the Abderhalden reaction to psychiatry, very little had been accomplished. Simon had shown that uniform results could be obtained in various psychoses, and Ludlum and White had also reported results with certain psychoses. In this preliminary report of the work at the New Jersey State Hospital they would merely present the results of the Abderhalden tests in 289 cases, including the various psychoses and some normal individuals. It was not their purpose to discuss the nature of the reaction or to take up the various theories that were represented by the various investigators. The original method of Abderhalden had been used in all cases, and in thirty-one cases the reaction was confirmed by the ice-incubation method of Bronfeubremer. It was important to remark that in the hands of one who had had considerable experience the reaction not only was of value as shown by the uniform reaction obtained in the same case on repeated examinations, but also that certain definite types of psychoses apparently had given uniform findings in a number of cases. We could conclude that the Abderhalden reaction gave certain definite and uniform results. That these results were practically negative except in dementia precox and epilepsy. That in dementia precox 81 per cent. of the cases showed a positive reaction to sex gland, and in three cases out of fifty-five gave a positive reaction to thyroid and sex; two of them were the catatonic type. Differential count of the blood showed rather characteristic conditions in dementia precox; *i.e.* high red blood cells, very low white cells, and high lymphocyte count and low polymorphonuclear. That in epilepsy practically all cases, sixty-nine, gave a positive reaction to adrenal gland. That the value of these reactions was to lay the foundation for therapy, based upon the facts deduced. In epilepsy the feeding of pancreatic gland had produced some remarkable results.

Injuries to the Spinal Cord Produced by Modern Warfare.—Drs. JOSEPH COLLINS and C. BURNS CRAIG of New York prepared this paper, which was read by Dr. Craig, who said that these observations were based on ten months' service with the American Ambulance in France. Contrary to what might be expected, the injuries to the nervous system were not different from those occasionally seen in civil practice. The great difference was quantitative rather than qualitative. All wounds to the nervous system might be grouped under three heads: concussion, contusion or laceration, and compression. Injuries to the peripheral nerves were practically all lacerations, compression from scar-tissue formation also playing a rôle. The lacerations of the brain and spinal cord presented a prognosis almost hopeless. Such cases showed little improvement in symptoms after the initial shock had passed off. Over 90 per cent. of the lacerated wounds of the brain, being infected, developed meningitis and died. Cases with cord lacerations remained paraplegic and died of sepsis following pyelonephrosis within nine months. Concussion injuries to the brain and cord cleared up in a most remarkable manner. Concussion with hematomyelia of the cord, causing paraplegia or quadriplegia, might follow the impinging of a bullet or shell fragment upon the vertebra without fracture of the latter. Such cases recovered almost completely.

Dr. CHARLES L. DANA of New York said he also felt in sympathy with Dr. Sachs' presentation, and it would be a great satisfaction if we as neurologists held some attitude which, as Dr. Sachs suggested, is one of full sympathy with the attempt to find organic conditions. He thought the association ought also to keep in mind the fact that before many years the whole situation would be changed by the enactment of laws of health insurance which would give compensation to every working man who earns less than $1,000 a year whenever he fell ill from any cause during his employment. We did not know exactly what the conditions would be, but it would revolutionize the activities of our dispensaries and hospitals and it would make great changes in methods of examining and compensating those who were injured nervously as well as from other causes.

Dr. F. R. FRY of St. Louis said that in regard to what Dr. Dana had been saying there was a better outlook for adjusting all these things between the profession and the laity by this industrial insurance feature than we had ever had. The difficulty had always been to have the general laity grasp the situation or have some means of handling it. He could not help feeling that that was going to be the solution of the whole thing.

Dr. L. F. BARKER of Baltimore said that we must distinguish between cases of incontestable organic and functional disease. There could be no doubt that there would be just as great disability from functional as from organic disease. He believed that in this matter psychiatry would help us. He thought that the organic neurologists were very apt to go too far in the direction mentioned, and that the psychiatrists would help us to get matters straight. He believed that the phobias and ideas of damages were very important, as they act on the susceptible nervous system. There was no doubt that when there was a single capital payment for damages the disease might last a shorter time than when payment was made by instalments. If invalid insurance should be adopted it seemed to him there might possibly be different rates of insurance for people who had a tendency to psychopathic conditions and those who are healthy and whose stock is healthy.

Dr. E. D. FISHER of New York City said that he would agree with Dr. Sachs in saying that not many of the cases were malingerers. They were honest in their statements. They were disabled; they were unable to do work; they would like to work, and he thought that was something we ought to consider.

Dr. B. SACHS of New York City said that the difficulties were extraordinarily great. He believed the neurologist and psychiatrist would have to co-operate in order to determine the exact mental attitude. He had brought to his notice cases of distinct chronic psychosis in which the disease antedated the time of the accident. For instance, one was a case of paranoia with delusions of persecution. It was the claim that the accident had made that paranoia worse.

The Report of the Cancer Control Commission.—Dr. HARVEY CUSHING of Boston said that at the meeting of this congress held in 1913 the American Gynecological Society presented to the other branches of the congress an identical resolution requesting the appoint-

ment of two or more delegates to co-operate in forming a national organization to conduct an educational propaganda regarding the prevention and cure of cancer. Of all the validated societies probably the Neurological Society had least interest in this, as cancer of the nervous system was of less immediate interest than cancer such as the laryngologist or the general surgeon or the gynecologist might encounter. Nevertheless it seemed to him that it would be just and fair and co-operative if that society would be willing to express its interest and sympathy in that movement and express its desire to co-operate and affiliate with it in any way in its power.

Dr. CHARLES L. DANA of New York City said that there was just one line of inquiry in connection with cancer of the nervous system which would be extremely interesting. He had seen, and probably all saw at times, cancer of the brain following operation upon the breast. This had come within his observation so often that he viewed with trepidation operation on the breast. If we sent in our experiences of metastatic cancer of the brain and spinal cord it would be helpful.

Dr. ALFRED REGINALD ALLEN of Philadelphia said that in compiling some statistics a few months back he and Dr. Frazier had been very much interested and not a little surprised to receive statistics from a well-known surgeon who made the statement that of all cases of cancer of the breast he had seen, a good many (70 per cent.) had given metastasis to the spinal column. We saw not only metastasis to the brain, but we quite frequently saw cord involvement through metastasis from the bone.

Dr. ARCHIBALD CHURCH of Chicago said that it had been his misfortune to see a number of women who had had cord metastasis from the breast during the last three years.

Dr. L. F. BARKER of Baltimore stated that he wished to speak of a practical point about the relief of root pain. We all knew how often morphine wore out and how big the dose had to be made. Schlesinger had put out a formula that had been used in the Johns Hopkins Hospital with great satisfaction. Two doses a day would usually keep the patient easy. The formula was as follows:

Scopolamine hydrobrom., 0.0025.
Morph. hydrochlor., 0.2.
Dionin, 0.4.
Distilled water, 10.
M. Sig.: Seven drops hypodermically every twelve hours or oftener.

It was a very small dose of scopolamine and of morphine, but it was remarkable how it relieved the pain.

Officers.—The following was the result of the election of officers: *President*, Dr. E. W. Taylor, Boston; *secretary-treasurer*, Dr. Alfred Reginald Allen, Philadelphia.

ASSOCIATION OF AMERICAN PHYSICIANS.

Thirty-first Annual Meeting, Held in Washington, May 9, 10 and 11, 1916.

THE PRESIDENT, DR. SEWALL OF DENVER, IN THE CHAIR.

Tuesday, May 9—First Day.

President's Address.—Dr. HENRY SEWALL of Denver made a brief address in which he referred to the influence and the records of the Association and believed that their best interests were to be had in casting out the weak and letting in the strong. In their ranks were a large number of men, rich in potential forces, men who were greatly to be welcomed. They should seek a broader intercourse with men and especially with those men who had recently entered their ranks. The Association had at present an issue which they should encourage, the plan for establishing a National Board of Examiners and he hoped that the work that the late Dr. Rodman had begun would be carried out. The menace which now confronted the race was that children in general seemed less and less imbued with the respect for truth; if this was a fact it was time for them to make some suggestions and consider methods for the correction of this. Scientific investigations were all desirable; truth itself demanded that they should seek the limitations of science. Faith, hope, and charity might add to what they were after—truth. So-called pure science was the indispensable servitor of truth. In all schools and colleges it had been agreed that the atmosphere that was surrounded by truth was ideal. Truth would rule the mind and the conduct of people.

Biochemistry of Acidosis.—Dr. LAWRENCE J. HENDERSON of Boston read this paper by invitation. He said that whatever the causes might be there was a common result which involved the normal chemical equilibrium. It was not at all difficult to discover the changes, or the largest change in the body. The great change was a diminution in the bicarbonates in the blood. The three elements to consider in the body with respect to the topic under discussion were (1) water, (2) sodium chloride, and (3) the bicarbonates. To understand how any diminution in the bicarbonates came about was not a difficult matter. It should be remembered that everything was related in the body to every thing else, and nothing was more far reaching in adjustment than this. The equilibrium to be maintained between acidosis and bases involves bases which could yield alkalies. The alkali was split off from the base, or probably from an unknown source, and the alkalies became mobilized. To treat a nephritis with large amounts of sodium chloride he believed was malpractice. On the other hand, nothing was easier than to treat acidosis with moderate quantities of an alkali. Small quantities of sodium chloride alone might render the urine neutral or faintly alkaline; then there would be no difficulty or ill effects from the acidosis.

Acidosis in Infants and Children.—Dr. JOHN HOWLAND of Baltimore said that acidosis in children was a dangerous condition, for after treating infants and children with this condition they must as a rule treat some chronic disease and with the constant fear that the acidosis might return. He divided acidosis into (1) that due to acetone bodies in excess, and (2) that not due to the formation of acetone bodies in excess. In acidosis there was nearly a complete anuria; the body could not rid itself of the acids and so developed an acid equilibrium. In nephritis in children acidosis might develop as it did in adults. It was quite generally assumed that the acetone bodies were abnormal and that their presence signified an unusual complication in the course of disease, whereas one might liken the mere presence of acetonuria to fever, for it occurred in most of the infectious diseases of childhood with much the regularity that fever did. The quantitative difference between the mere presence of the acetone bodies and their production in sufficient amount to threaten life was an enormous one. To guard against the deleterious influence of acids formed or introduced into the body, a most efficient mechanism was available. It was only necessary to consider the mechanism from the standpoint of the blood since this served to regulate the reaction for the entire body. The important constituents of the blood influencing this regulation of the reaction were sodium bicarbonate, occurring chiefly in the plasma; the acid and alkaline phosphates of potassium, found almost entirely within the red blood cells, and the proteins. Acids, whether formed in the body or introduced from outside, displaced the carbonic acid from the sodium bicarbonate and set carbon dioxide free. This excess of carbon dioxide was removed by the increased pulmonary ventilation, leaving a neutral salt, sodium oxybutyrate, or chloride, or what not, to be removed by the kidneys. Such a mechanism allowed relatively large amounts of abnormal acids to be at once rendered innocuous and removed. Thus dyspnea, or more properly hyperpnea, under abnormal circumstances, was an agent of the greatest value in ridding the body of carbon dioxide and keeping the reaction within normal limits. Hyperpnea was the best evidence of acidosis to be obtained by physical examination alone. The second defense of the body by which acids were removed was elimination by way of the kidneys; these have the capacity to excrete an acid urine from a nearly neutral blood. The third method of defense was offered by the proteins and depended upon their amphoteric character. These three means of defense acted synchronously and resided in the blood itself. The body possessed a further means of defense in that it was able to neutralize acid by the production of alkali in the form of ammonia. In childhood acidosis resulting from the production of abnormal acids was found chiefly in diabetes and recurrent vomiting. A study of diabetes in children showed very well the enormous amount of acid that might be taken care of with no disturbance of the reaction of the blood and with no effect upon the respiration. In recurrent vomiting the conditions were more obscure and less understood than in diabetes.

Acidosis in Acute and Chronic Disease.—Dr. CHANNING FROTHINGHAM of Boston said that with the improvements in the methods now employed in detecting

acidosis the subject had increased tremendously in interest in recent years. The occurrence of acidosis in diabetics had long been known. Recently one of the profession had shown and demonstrated to us that in a great many of the acute infections and diseases of childhood this condition was present. During the past winter in Boston the cases had been studied as they came in and it was learned that acidosis occurred among adults as it did in children.

Investigations in Diagnosis and Treatment of Acidosis.—Dr. L. G. ROWNTREE of Baltimore, Md., described a method of diagnosis which he said was very simple and rapid, fifty demonstrations having been made in one afternoon. He thought the nomenclature of this disease should be considered by the Association. With regard to acidosis in diabetes he reported briefly one case in which all known methods of treatment had been applied. Alkalies were given in sufficient quantity to correct the hydrogen-ion concentration, in other words, the blood became alkaline; but in spite of this the hydrogen-ion concentration (the acetone bodies) in the blood persisted in twice the normal amount, and then the patient died in an attack of typical diabetic coma. This went to show that one could correct the acidosis without changing the patient's condition.

The Etiology of Pellagra.—Dr. EDWARD J. WOOD of Wilmington, N. C., presented this subject from the standpoint of a deficiency, but this deficiency was regarded as more specific than had been generally thought. Corn was thought by the writer to bear the same relation to pellagra as rice to beriberi. The evidence of the correctness of this view was proven both by experimentation on the pigeon and by evidence found in the literature of outbreaks of pellagra brought about by eating highly milled meal which were promptly controlled and corrected by feeding whole meal. The fault lay in two factors. The first was the heating of corn in the kilns above 120° C., which was enough to destroy the vitamine. The second was the removal of the fat containing germ from the grain. The remedy consisted in feeding the victims the whole grain and this plan was also prophylactic.

The Treatment of Typhoid Fever by Intravenous Injections of Sensitized Typhoid Vaccine Sediment.—Drs. FREDERICK P. GAY and H. T. CHICKERING of the University of California presented this communication. This report dealt with slight amplifications of the cases already given by the authors. It included a number of additional cases and also a continuation of the laboratory studies. The series consisted of between 75 and 80 cases of typhoid fever in which the diagnosis had been verified by blood culture and the Widal tests. In these cases the majority had been treated with intravenous injections of polyvalent, sensitized typhoid vaccine sediment as already recommended for prophylactic use by Gay and Claypole. The routine treatment of these cases, apart from this specific treatment, had varied somewhat, as the cases occurred in the practice of a large number of physicians, and both in hospitals and private houses. The mortality had been about the same as the best hospital normal, from 9 to 10 per cent. Very distinct benefit, however, had been produced by the vaccine treatment in cutting short the duration of the disease. Over 40 per cent. of the cases had been abortively cured, that is to say, the temperature had returned to normal within a week following the first use of the vaccine. In 25 per cent. more of the cases each injection of the vaccine had been followed by a successive fall in the temperature level and a more gradual return to the normal temperature in periods that had been distinctly affected by the treatment. The nature of the reaction produced by these injections and the correlation of the severity of the disease and the blood findings in relation to the results produced, would be considered as well as suggestions that might be useful in still further perfecting this method of procedure in the near future.

The Physical Signs and Symptoms of Wounds of the Chest.—Dr. C. P. HOWARD of the University of Iowa reported a series of 107 cases, of which 87 were thoroughly studied. The wounds were produced by rifle or machine-gun bullets (45) or by shell as shrapnel, high explosive, or hand grenades (42). In one group (15) no signs could be found. In Group II either pneumonia (4) or simple serous effusion (2) was found. In Group III mediastinitis (one case). In Group IV a hemothorax was found which was either infected (9 cases) or non-infected (56 cases). The infecting organisms varied. The symptoms were cough, pain, hemoptysis of varying degree and dyspnea. There was usually fever present. The physical signs suggested rather a consolidation than fluid owing to the great compression of the lung. The cardiac displacement was often striking. In eight cases unequivocal and in five others suggestive signs of pneumothorax were present. In four cases a pneumonia existed on the side opposite the hemothorax. Secondary hemorrhage into the pleural cavity was rare, only one case being noted. Simple fibrinous pericarditis occurred in three cases and in one a pneumopericardium. The treatment consisted of free drainage in the infected cases and of simple aspiration or of oxygen-replacement. The mortality was only 7 per cent. in the entire series.

Wednesday, May 10— Second Day.

Election of Officers and Members.—*President*, Dr. George Dock; *Vice-President*, Dr. Francis H. Williams; *Secretary*, Thomas McCrae; *Recorder*, Dr. Thomas R. Boggs; *Treasurer*, Dr. J. P. Crozier Griffith; *Councillor*, James B. Herrick; *Representative on the Executive Committee of the Congress of American Physicians and Surgeons*, Dr. Theodore C. Janeway; *Alternate*, Dr. Richard P. Strong.

Elected to Honorary Membership.—Dr. William C. Gorgas, Surgeon General, United States Army; Dr. George M. Kober, Washington.

Elected to Active Membership.—Dr. Charles C. Bass of New Orleans; Dr. Nellis B. Foster of New York; Dr. J. Ramsey Hunt of New York; Dr. James W. Jobling of Nashville; Dr. Howard T. Karsner of Cleveland; Dr. Francis W. Peabody of Boston; Dr. Peyton Rous of New York; Dr. Walter R. Steiner of Hartford, Conn.; Dr. Albert E. Taussig of St. Louis, Mo.; and Dr. Rollin Turner Woodyatt of Chicago.

Elected to Associate Membership.—Dr. Frederick M. Allen of New York; Dr. Alphonse R. Dochez of New York; Dr. Charles W. Edmunds of Ann Arbor; Dr. John H. Eyster of Madison, Wis.; Dr. Arthur D. Hirschfelder of Minneapolis; Dr. Arthur S. Lovenhart of Madison; Dr. Herman O. Mosenthal of Baltimore; Dr. Edward Carl Rosenow of Rochester, Minn.; Dr. George C. Shattuck of Boston, and Dr. Gerald B. Webb of Colorado Springs.

Lipase in the Urine of the Tuberculous.—Dr. WILLIAM CHARLES WHITE read this paper. He undertook a study of the lipase in the urine in tuberculous patients and found that there was a disappearance of fat in the animal body, and also an accentuation of the destructive process itself in the animal bodies succumbing to this disease. The fact that lipase act on the tubercle bacillus itself had also been shown. In all 194 separate tests had been made and the very useful method of Hulet was used; this method was published years ago. In order to rule out the possibility of the influence of food, etc., he took all the urine passed at each time for six days. In one case 19 separate tests were made, in another, 28; in another, 42, and in another 9. All were distinct cases of tuberculosis and in a dying condition. There were 73 tests made in the early cases, cases that were improving and those that had no fever. In one case of pneumonia with high fever and in one case with typhoid fever, a number of tests were made. In conclusion Dr. White said that in the urine of normal individuals, apparently normal, with tuberculosis and without fever, there was no lipase. They were practically normal individuals. In the urine of the advanced cases with fever and oncoming fatality, there was a marked variation in the lipase content. The increase in the lipase content preceded the accompanying fever. There was no lipase in the cases of pneumonia when there was a high fever.

Leucemia, Lymphosarcoma, and Hodgkin's Disease.—Drs. C. H. BUNTING and J. L. YATES presented this communication, and called particular attention to the difficulties encountered in making the diagnosis. There was a group of diseases in which the gland enlargement was a feature of the disease. To summarize the common factors there was the presence of the history of primary infection as well as some trouble in the buccal cavity. There was this progressive glandular enlargement with or without tumors. There were moderate anemia and a late fever. There was a fatal termination in all the cases. There was the occurrence of a true course of the disease, Hodgkin's blood picture or the leucemic blood picture. Bacteriologically the condition was characterized by considering the presence of the diphtheroid organism. Pathologically they might place the disease into one of three groups. First, the Hodgkin group proper; here they met with a marked destruction of the lymphocytes and a proliferation of

the endothelial cells and fibroblasts. In this group they often found the leucemic blood picture. Secondly, this was the group of the so-called large-celled lymphoma, a group commonly called pseudoleucemia. Thirdly, there was the group of small-celled proliferation, a lymphocytoma. The evidences all pointed to the etiological value of the diphtheroid organism.

Renal Function in Serum Disease.—Drs. W. T. LONCOPE and F. A. RACKEMANN presented this report. During the past two years they had made a careful study of renal function in ten cases and the method employed was placing the patients on a diet consisting of a certain amount of sodium chloride and then determining the output in the urine. The charted results were very interesting.

Studies of the Actual Constituent, in Crystalline Form, of the Thyroid.—Dr. E. C. KENDALL of Rochester, Minn., read this paper. He said that the investigation of the iodine compound isolated from the thyroid, had shown that it possessed the characteristic activity of the gland and was its actual constituent. Its isolation in pure crystalline form had been perfected, and preliminary experiments suggested that its function was concerned with the metabolism of amino acids.

The Pathological Changes in the Sympathetic System in Goiter.—Dr. LOUIS B. WILSON of Rochester, Minn., presented this paper, which was illustrated with lantern slides. The paper was based on a study of cervical and other sympathetic ganglia removed at operation and from patients with goiter, the results being controlled by a study of the ganglia from non-goitrous patients. Sections of the ganglia, stained by various methods, showed extensive histological changes, consisting of various stages of cell degeneration, viz., hyperchromatization, hyperpigmentation, chromatolysis, and atrophy or granular degeneration. So far as might be determined from the small number of specimens examined (25 cases), the pathological changes in the ganglia were paralleled to the stage and intensity of the symptoms of hyperthyroidism and to the hyperplastic and regressive change in the thyroid.

Dissociate Jaundice. — Drs. C. F. HOOVER and M. A. BLANKENHORN of Cleveland presented this communication in which they told of the methods employed in detecting bile pigment in plasma and in the urine, the method of isolating the bile salts in the urine, etc. Dissociate cholemia and dissociate choluria might be correlative in many cases, and not the consequence of dissociate biliary retention. Pigmental jaundice without bile salts was invariably hematogenous and never originated from dissociated hepatic retention of bile pigment. Pigmental choluria without bile salts was frequently a survival of complete biliary retention. Pigmental choluria without bile salts occurred only in hematogenous jaundice. Bile salts were not present in hematogenous cholemia. Bile salts unaccompanied by bile pigment might have occurred in the blood of primary anemia and lead poisoning. Bile salts unaccompanied by bile pigment might occur in the urine as a consequence of dissociated retention of bile salts in primary anemia and lead poisoning. The presence of bile salts in the urine without bile pigment was (with primary anemia and lead poisoning excepted) always due to renal dissociation of complete cholemia on account of the absorption of bile pigment in the plasma and the escape of bile salts through the renal filter. The maximum cholemia (pigmental) without choluria might be both hematogenous and hepatogenous. Obstructive jaundice yielded only moderate cholemia and choluria. When cholemia was pronounced from obstructive jaundice, choluria would develop. In hemolytic and infectious jaundice there might be pronounced cholemia without choluria.

Pancreatic Changes in Latent Syphilis. — Dr. A. S. WARTHIN of Ann Arbor, Mich., read this paper, which he illustrated with lantern slides. The histological study of the material from seven autopsies in deaths from diabetes showed in all syphilitic lesions in the myocardium and aorta, the presence of spirochetes being demonstrated in five cases. In all of these cases marked changes were found in the pancreas of the nature of interstitial pancreatitis, both interlobular and intra-acinar. This led to the study of the pancreas in a large number of other cases of latent syphilis with the result that in no case was a normal pancreas found. In all cases of latent syphilis this organ showed marked changes in the form of a diffuse or patchy fibrosis with active inflammatory foci corresponding to the localization of the spirochetes. The relationship of these changes to diabetes was discussed.

The Control of Malaria by Treating Malaria Carriers. —Dr. C. C. BASS of New Orleans presented this paper, which was illustrated by lantern slides. Where malaria prevailed there were many more malaria carriers who were not known to be infected than there were persons who had acute symptoms of malaria. In much of the country where malaria prevailed it was not practical at present to install and maintain measures that would prevent the breeding of mosquitos, nor to protect all the inhabitants, including the carriers, from their bite. Koch advocated the possibility of control and eradication of malaria by finding and treating all infected persons in the community. Experiments and a demonstration of this method on a large scale were now being made in Bolivar County, Miss., in the heart of the malarial section of the South. The work had advanced sufficiently to show that in this county, which was believed to be representative of a large part of the South in which malaria was most prevalent, the cooperation of all the people could be secured to the extent of making a complete malaria survey and inducing all to take quinine as directed. The cost of the control of malaria by such a method would be very small compared to the cost of controlling it by the known methods of mosquito control. Lantern slides were presented showing the prevalence of malaria, the importance of the malaria carriers, and some of the results obtained in this experiment.

Clinical Observations on Intestinal Autointoxication, Especially as Regards the Specificity of Toxin. — Dr. THOMAS R. BROWN of Baltimore presented a study of two cases of chronic eczema and urticaria of long standing, with definite hypersensitiveness to various proteins, and of a case of choroiditis apparently due to definite infection of intestinal origin.

The Bile Content of the Blood in Pernicious Anemia.— Dr. A. M. BLANKENHORN of Cleveland presented this paper. He said that while investigating the nature of the jaundice in pernicious anemia, the observation was made that many patients, although distinctly jaundiced, showed no bile in the urine. The blood plasma, however, in every case showed a corresponding jaundice. These plasmas when presenting a jaundice of certain intensity all gave a chemical test for bilirubin. Urobilin was found in the plasma of none. There was often a higher concentration of bilirubin in the plasma, coincident with the absence of bile from the urine, than was found in the plasma of patients with certain lesions of the liver which were always characterized by bile in the urine. Bile salts were found in the plasma in ten out of thirteen cases. The cases showing the highest concentration of bilirubin in the plasma were those showing evidence of the most active blood destruction, that was, anemia, jaundice, and increased urobilin in the stool and urine. The cases showing highest concentration of salts were those in which the nerve lesions predominated.

Anatomical Approaches to the Problem of the Functional Psychoses, Including a Particular Study of Five Brains.—Drs. E. E. SOUTHARD and M. M. CANAVAN of Boston presented this paper, which they illustrated with lantern slides. They stated that at the bottom of all work with the functional psychoses should be a series of cases anatomically verified. Massachusetts institutional material had been culled to secure such a series, and a summary of previous published work was offered. New York with Boston State Hospital material was offered from which by successive refinements and eliminations a series of five cases was obtained from an initial group of over 150, in which five cases a number of somewhat equivocal microscopic appearances were found, sometimes in remote parts of the cerebral cortex not often examined. These cases were all of long-standing, yet had brains of approximate normality in the gross (systematic photography available). The problem of the essential functionality of these five cases was then considered. Were there cases of severe chronic mental disease in which the brains were intrinsically normal?

The Roentgen Ray in the Diagnosis of Cancer of the Stomach.—Drs. JULIUS FRIEDENWALD and F. H. BAETJER of Baltimore presented this communication, which they illustrated with lantern slides. In the *x*-ray study of cancer of the stomach, they said it was important to recognize the varying positions and functions of the stomach under normal conditions. The greatest difficulty arising was that the stomach was not a hard fixed subject, for they knew that a perfectly normal stomach might present great variability, not only as to position, but as to motility and expulsion of contents.

We might divide the various types of stomach into three classes—first, the stomach of the fleshy individual; second, the stomach of the medium weight individual, and third, the stomach of the thin individual. We had no hard and fast rule, therefore, according to which the stomach could be said to empty in a certain number of hours and that if this time was prolonged, that the conclusion was reached that we were dealing with some pathological condition. In the first class, the stomach emptied in about three hours. In the third class it took about six hours, and so that the question of any beginning obstructive lesion was dependent very largely on the character of the stomach with which we were dealing. A third difficulty was to be encountered in the fact that the motility of a normal stomach might be naturally affected by conditions outside of the stomach itself. In dealing with carcinoma of the stomach their determination of the special lesion was dependent upon the study of several conditions. Namely, the peristaltic waves of the stomach and the many irregularities or filling defects in the stomach itself. We might divide the carcinomatous lesions of the stomach into three classes: first, lesions in the cardiac end of the stomach; second, lesions in the body of the stomach, not affecting the orifices; third, lesions at the pyloric end of the stomach. The carcinomatous lesions of the various portions of the stomach varied materially and had their characteristic *x*-ray pictures. Differential diagnosis between carcinoma and ulcer was often most difficult. The *x*-ray often furnished important evidence as to whether the tumor was or was not operable in as much as it definitely established the location and extent of the growth and degree of obstruction.

The Main Factors Affecting the Intensity of the Sounds as They Pass from the Interior of the Lungs to the Periphery of the Chest. — Drs. GEORGE W. NORRIS and C. M. MONTGOMERY of Philadelphia presented this paper which they illustrated with lantern slides. They stated that the main factors diminishing the intensity of sounds as they passed from within the bronchi to the external chest surface were reflection and diffusion. Reflection might be a potent factor where vibrations passed between media of different densities as air and fluid or air and tissue. Sound was not much affected in its passage between fluid and tissue because the differences in density were not sufficiently marked. Marked vocal resonance occurred over solid lung because the parenchyma was airless, thus eliminating reflection in this part of the lung. The vocal resonance might also be increased when fluid separates a solid lung from the chest wall. In the normal lung, on the other hand, reflection took place between the bronchi and the surrounding air, between the tense membranous tissues of the parenchyma and the adjoining air, and between the air in the lung and the chest wall. Diffusion, while more or less a constant factor in all conditions, plays a special part in pleural effusion, the sounds becoming spread out or diluted as they pass from the lung surface in contact with the fluid to the point on the chest revealing diminished vocal resonance.

(To be continued.)

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

RULES FOR RECOVERY FROM PULMONARY TUBERCULOSIS. A Layman's Handbook of Treatment. By LAWRASON BROWN, M.D. Published by Lea & Febiger, Philadelphia and New York. Second Edition. Thoroughly revised. 184 pages. Price, $1.25 net. Cloth.

PROFILAXIS DEL TIFUS EXANTEMATICO. Por el DR. D. MANUEL MARTIN SALAZAR. Published by Enrique Teodoro, Madrid. 59 pages.

TRANSACTIONS OF THE THIRTY-SEVENTH ANNUAL MEETING OF THE AMERICAN LARYNGOLOGICAL ASSOCIATION. Held at Niagara Falls, Canada, June 1, 2, and 3, 1915. Published by the Association, N. Y. 402 pages.

ON MODERN METHODS OF TREATING FRACTURES. By ERNEST W. HEY GROVES. Published by William Wood & Company, New York. Illustrated. 286 pages. Price, $2.75 net.

Therapeutic Hints.

Roentgentherapy of Venereal Bubo.—E. Kilbourne Tullidge mentions a good and efficacious treatment for venereal bubo which he says was accidentally discovered by a German medical officer in charge of a mobile Roentgen apparatus in the field. He treated the inflammatory swellings symptomatically with roentgentherapy (10-20 X with a 0.5 mm. aluminum filter) with the result that fluctuation, pain, redness, and swelling gradually disappeared and the retrogressive changes that followed left only a small pigmented spot on the scar.

Calcium Sulphide in Bichloride Poisoning.—In the MEDICAL RECORD of July 1 (p. 29) reference was made to Rickett's recommendation of calcium sulphide as an antidote to bichloride of mercury. For every grain of mercury which has been taken he gives one grain of calcium sulphide by the mouth and repeats it every two hours until five doses have been taken. In the item referred to this was erroneously written five grains instead of five doses.

Purgative Rendered More Palatable.—One-half teaspoon of aromatic spirit of ammonia added to a dose of salts improves the taste and removes the nauseating effect for most patients.—*The Nurse.*

Orange Peel as a Cholagogue and Peristaltic Stimulant.—Rosenthal, a medical officer on active service with the French army, has been using plain orange peel prepared in the following manner as a means for improvement of the intestinal conditions of the soldiers in his charge: Fresh orange peel is boiled in about a pint of water for half an hour; this water is removed and may be used for a tooth wash. The softened peel is then boiled for another half hour in fresh, slightly sweetened water, removed and dried, when it is ready for use. The peel of one orange is an average dose. While the intestine is acted upon mechanically, there is also an increased flow of bile which may continue for several hours.

Ammonia as an Enema.—T. A. Black offers the following prescription for an enema to be used in the treatment of postoperative abdominal conditions where ileus and intestinal paresis may be present: Liquor ammoniæ fortior, 1 dram; water, 1 pint; a hypodermic of pituitary extract, 1 c.c., given half an hour before the enema produces an increased effect. The enema must not be used too frequently or in succession, or any stronger than the prescription above given, as otherwise injury to the intestinal mucous membrane is liable to occur. The enema produces a large movement and discharge of flatus.—*The Lancet.*

Another Use for Epsom Salts.—A saturated solution of Epsom salts applied to linen stained by iodine entirely eradicates the stain without injury to the material.—*The Trained Nurse.*

A Harmless Antiseptic Dressing.—Where personal idiosyncracy contraindicates the use of bichloride as a dressing for wounds, erysipelas, etc., the following answers as a general antiseptic:

℞ Sodium citrate, 0.5.
Sodium chloride, 3.0.
Distilled water, 100.0.

Prevention of Bed Sores.—

℞ Sodium chloride, ʒij.
Whiskey, Oj.

M. sig.: Apply to parts twice daily.—*Western Medical Times.*

CULTIVATION OF THE ORGANISMS OF VACCINIA, VARIOLA, AND VARICELLA.

BY HORACE GREELEY, M.D.,

BROOKLYN, N. Y.

IN the MEDICAL RECORD of Aug. 1, 1914, I gave an account of a diplococcus-like organism which I had "found to be constantly present in vaccinia virus, in vaccine vesicles, in varicella vesicles, and in the vesicles and pustules of such cases of variola as had been available." Since this time I have been studying the behavior in cultures of the organisms, and investigating various serological and immunological factors in connection therewith. In the present article I will recount some cultural experiments that may be easily performed by anyone, and detail other work which I have completed.

Appearances in Vaccinia Virus.—If a dilute smear be made of any specimen of commercial vaccinia virus or of Noguchi's rabbit-testicle preparation,* or of lymph from a human vaccine vesicle, and the smear be fixed and stained by one of the ordinary methods—preferably first "clearing" the specimen with 50 per cent. acetic acid—and care be used to avoid the formation of dye precipitates, a good many distinct, though minute, bipolar bacilli may be seen with aid of the usual oil immersion (1/12) lens and a magnification in the neighborhood of 1000 diameters. After one has detected these organisms and has made out that portion of their bodies, usually non-stain-taking, lying between their well staining poles, many oval non-stain-taking involution forms† may be seen, which in view of the cultural history (to be detailed), are probably in the process of "spore" formation or discharge. These latter are commonly very numerous in lymph from human vaccine vesicles.

Cultures from Vaccinia Virus.—Originally, cultures were made in pure hydrocele fluid, completely filling the hollow between a hanging-drop slide and its cover glass, the margin of the latter being sealed with paraffin. In such a culture, after two days, with the ordinary 600 magnification, a great many minute bipolar bacilli may be seen (as tiny globules) and clumps of branching organisms are numerous at the end of six days. In such fluid media all the organisms show a greatly exaggerated Brownian movement which tends to separate all daughter cells from their parents. Subcultures from such slides on ordinary solid media show no developments.

*Specimens of "strains No. 86 and No. 100" were used.

†In the Noguchi preparation such "spores" are not in evidence. This explains the relative short life of the rabbit testicle virus as compared to the skin produced vaccine.

In testing the suitability of various strengths of hydrocele fluid, several series of cultures were made, with the average results shown in the following table:

TABLE I.

HYDROCELE-FLUID-DILUTION MEDIA TESTS.

Each tube contained approximately 2 c.c. of total fluids; each was planted with one drop of one-in-ten vaccine virus (in saline solution, and taken from a market tube of virus); each had a blank control, and all were incubated, aerobically, at 37.5 deg. C.

	RESULTS—END OF SIX DAYS.	
Hydrocele Fluid Strength (Diluted with Salt Solution), per Cent.	Macroscopic	Microscopic
10, 15 and 20	0	Occasional bipolar bacillus.
25 and 30	Faint precipitate	Few bipolar bacilli.
35, 40, 45, 50, 55, 60	Slight precipitate	Many bipolar bacilli.
65,70, 75, 80, 85, 90, 95, 100	Faint precipitate	Few bipolar bacilli.

With 50 per cent. hydrocele fluid as a constant, and allowing for the saline contents of hydrocele fluid, the salt concentration of the media was increased in multiples of 0.9 per cent sall strength, with results as in the following table:

TABLE II.

SALINE CONCENTRATION EFFECTS.

Salt (0.9 per Cent.)* Concentration, Per Cent. of Total.	RESULT, END OF SIX DAYS.	
	Macroscopic.	Microscopic.
20	Very slight sediment	Few small bipolar bacilli.
33	Moderate sediment	Many small bipolar bacilli.
50	Heavier sediment	Great many bipolar bacilli.
100	Slight sediment	Few very small bipolar bacilli.
127	Slight sediment	Few very small bipolar bacilli.
160	Faint sediment	Few very small bipolar bacilli.
200	Faint sediment	Few very small bipolar bacilli.
250	0	Occasional one.

*Made from tablets each containing: sodium chloride, 2.250 gm.; calcium chloride, 0.075 gm.; potassium chloride, 0.025 gm. Four tablets to the liter used to make all the salt solutions. Same tablets were used in making bouillon. It is not thought, however, that the results would be any different with a 0.9 per cent. salt base of pure sodium chloride.

From the results given in Table II it was judged that a salt concentration of 50 per cent. was most suitable as a diluent. Therefore, using sterile distilled water in place of the saline recorded in Table I, a similar series of tests was carried out, with a similar result, only that the growth of organisms in each dilution was considerably greater (particularly so in tubes containing 50 per cent. hydrocele) than in the tubes of the series of Table I, and corresponded in development to "50 per cent." of Table II. To the last described favorable medium (50 per cent. hydrocele in distilled water) was then added glycerin in percentages from 0.1 to 50, and the same general procedure gone through with as before; and, while it was found that the addition of glycerin in all proportions exercised a slightly

unfavorable influence, still a few bipolar forms appeared in all strengths up to and including 5 per cent. glycerin. (It should not be forgotten that this applies to direct cultivation from vaccinia virus.)

In the course of many trials of various culture media it was found that after washing the surface of an ordinary Loeffler blood serum tube with lime water, a plant of vaccine virus would often yield a faint growth, which, though barely discernible macroscopically, supplied many bipolar forms to smear examination. On this account a series of cultures was made, as before, in 50 per cent hydrocele and distilled water, to which latter calcium oxide had been added in amounts to make the series of tubes contain a lime water (0.17 per cent. calcium oxide) strength running from 1 to 50 per cent.

After three days incubation, it was found that tubes containing lime water equivalent strengths between 1 and 20 per cent. showed heavier growths than controls without the calcium oxide. (It should be noted that tubes holding a lime water equivalent of 25 per cent. and over showed a distinct precipitate immediately after preparation.)

Bouillon was then substituted for the distilled water, and a series of tubes (containing 2 c.c. each of total fluid) was inoculated, and the same general procedure followed. After six days' incubation the results were as shown in Table III.

Dextrose added to the fluid media, even to the extent of 0.1 per cent., proved to have an unfavorable influence upon growth of the organism (on direct cultivation from virus).

TABLE III.

LIMED HYDROCELE-BOUILLON TESTS.

Lime-water-equivalent strength of media, 10 per cent.

Hydrocele Fluid, per Cent.	Bouillon, per Cent.	Macroscopic Appearance	Microscopic Finding
0	100	Faint precipitate	Few bipolar bacilli.
50	50	Marked precipitate	Many bipolar bacill
62 5	37 5	More marked precipitate	Great many bipolar bacilli.
75	25	Still more marked precipitate	Great many bipolar bacilli
87 5	12 5	As next above	Many bipolar bacilli.
100	0	None	Few bipolar bacilli.

From Table III it is seen that media consisting of about 70 per cent. hydrocele fluid and 30 per cent. bouillon, and containing a lime water equivalent of 10 per cent. (*i.e.* 0.017 per cent. calcium oxide) was quite suitable for the growth of the organism in question. Wishing to exclude more positively possibilities of the presence of organisms contaminating the hydrocele fluid, equal parts of bouillon, and the distilled water with various percentages of lime water, were tried and it was found that approximately 50 per cent. of bouillon, with 50 per cent. of distilled water—water from 10 to 100 per cent. saturated with calcium oxide—was very suitable for cultivating the bacillus.*

*In hanging-drop slide cultures, in medium composed of diluted hydrocele and sterile powdered guinea-pig skin, branching groups were observed in which no segmentation of central filaments could be seen, while terminal projecting filaments commonly developed spore-like bodies. This gave rise to the belief that the organisms were of the sporothrix variety. Subsequent free cultivation, however, showed their true nature.

TABLE IV.

GENERAL RESULTS—FLUID MEDIA (AS SHOWN BY A SERIES OF CULTURES SOWN WITH VACCINIA VIRUS).

Culture No.	Hydrocele, per Cent.	Bouillon, per Cent.	Diluent: Distilled Water	Diluent: 0.9 per Cent. Salt Solution.	Lime Water Equivalent, per Cent.	After Three Days Incubation: Macroscopic.	After Three Days Incubation: Microscopic.	After Five Days	Second Day Replant, Five Days, Loeffler.	Fifth Day Replant, Two Days Growth on Loeffler: Macroscopic.	Fifth Day Replant, Two Days Growth on Loeffler: Microscopic
1	100					Clear*	Few bipolar bacilli				
2	50			50		Clear*	Few bipolar bacilli				
3	25			75		Cloudy	Many bipolar bacilli	Large bipolar bacilli, surface gr'th		Profuse	Small and large bipolar bacilli

25	50	50			**	Clear	As 12				
26	33	33		34	10	Cloudy	As 5	As 3		As 3	As 3
27		100				Clear	As 4				
28		50	50			Clear	As 5		As 5		
29		100			10	Clear	As 5		Sporulating bipolar bacilli		
30		50	50		10	Clear	As 12				

*Nearly all tubes showed some precipitate.
**Small piece of calcium carbonate added.

In preparing this medium, calcium oxide (Merck) was used, a small quantity being recalcined on a piece of platinum foil and dumped into a test-tube containing bout 4 c.c. of distilled water, the latter having just been boiled to expel the carbon dioxide. This tube was then centrifuged and the required proportion of the clear lime water was added to a tube containing bouillon, also just boiled with the same object.

Table IV is useful mainly to show in what varied media the vaccinia organism may be grown, and also that for a particularly successful transplant the sporulating stage must have been reached. Further, that this latter can be reached only under

Note. In this table the extent of agglutination is indicated as follows: No agglutination, O; slight, S; partial, P; complete, C.

aerobic conditions (note cultures 3, 6, 8, 11, 14, 19, 24, 26, from which highly successful transplants were made, and also cultures 5, 7, 10, 17, 28, whose transplants produced no macroscopic growth.

It is also apparent from this and the preceding tables that there is some element in both hydrocele fluid and bouillon that needs to be neutralized, or at least diluted, before much growth (primary plant) of the organism can take place. (In Table IV compare cultures 1, 3, and 6; 27, 28, and 29.)

It was some time before the appearance of large bacilli among the minute bipolar affairs was understood, since the temptation was to regard them as but contaminations, and it was not until the method of cultivating the organism upon solid media was discovered that any certainty was felt as to their rôle.

As a result of attempts (some successful and some not) to transplant the fluid cultures to solid media, direct cultivation of vaccinia virus upon solidified blood serum was essayed. Remembering the rôle of the limed bouillon in fluid cultures, and knowing the necessity of keeping cultures from drying; besides thinking of imitating the natural process by which the host's circulation carries off what may be called a parasite's sewage, the following procedure was adopted: The surface of an ordinary Loeffler blood serum tube was inoculated with a loopful of 10 per cent. vaccinia virus (in saline solution or distilled water) and upon this was dropped one or two drops of limed bouillon (bouillon 50 per cent. in distilled water from 10 to 100 per cent. saturated with calcium oxide). Tube was incubated at 37.5° C., and each day a drop or two of freshly prepared limed bouillon was made to flow over the surface of the media. In any case in which bouillon accumulated sufficiently to threaten to drown the culture it was pipetted off.

In cultures so treated there appears in about ten days, sometimes earlier, sometimes much later, a crop of low lying (flat) mucus-like, glistening colonies which, usually within 24 hours after they appear, begin to cause rapid peptonization of the media.

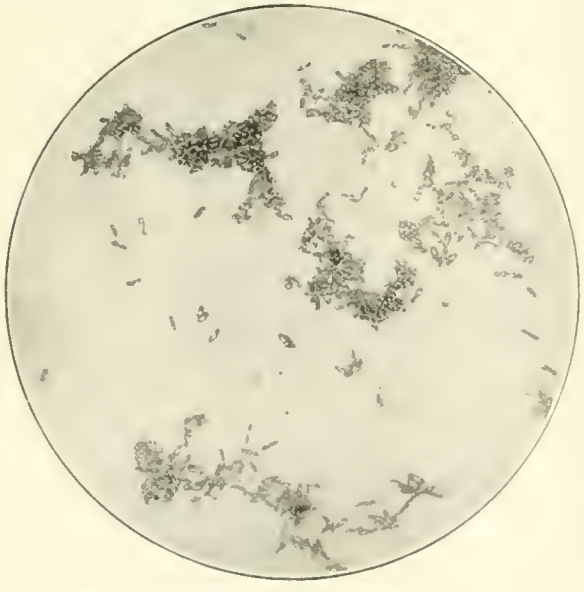

FIG. 1—Primary culture of vaccinia virus on Loeffler. Seventh day. Organism "sporulating." Stained by alkaline methylene blue. Magnification 1650.

Transplantation from such colonies on ordinary Loeffler serum gives rise, within 24 hours, to a profuse growth which usually covers the entire surface of the media and sometimes becomes wrinkled and curdy. Peptonization, with replants, begins quite uniformly within 24 hours. Transplanted to nutrient agar growth is uncertain but sometimes

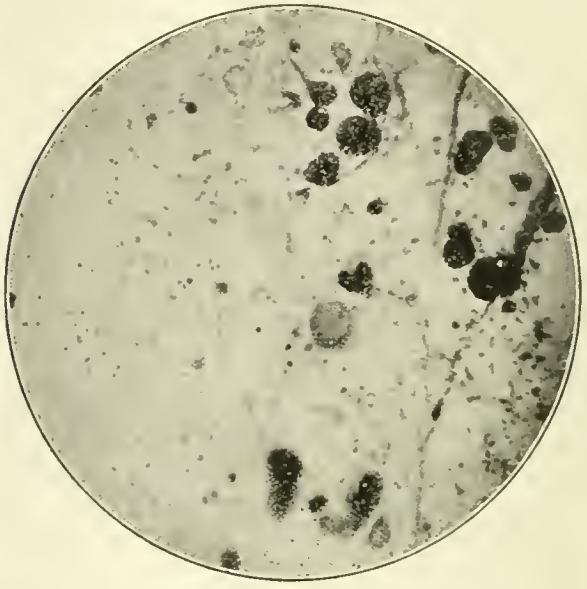

FIG. 2—Smear from pustule of S. A., a negro patient of the Kingston Avenue Hospital. Made at the height of a generalized variola eruption. Smear cleared with 50 per cent acetic acid, and then stained by alkaline methylene blue. Magnification 1650. It is seen that only the poles of many of the bacilli are stained.

(after extended artificial cultivation commonly) similar. Transplanted to bouillon, within 24 hours the medium is clouded, and sometimes a white matted growth appears a day or so later upon the surface. From the minute, bipolar, poorly staining bacillus of vaccinia virus we find in the fluid primary cultures described, after some three days, besides the same minute forms, large well staining bacilli, and others of intermediate size.

In the colonies which have developed upon solid media, as described, only the largest forms are to be seen, in various stages, either not distinctly showing the bipolar effect or with this very marked. Within 24 hours (after the first appearance of these solid media colonies) the organisms begin to "sporulate" (simultaneously with their peptonization of the media) when they show as non-staining centrally, oval-shaped bodies with a tiny "spore" in each end.* After the peptonization of the media is well advanced (within two or three days) nothing but the "spores" can be found, many appearing like the primary minute bipolar bacillus of vaccinia virus and young primary fluid cultures. These "spores" when planted in concentrated hydrocele fluid media usually develop only the minute form, so that by this procedure the organism can be restored to its vaccinia virus stage, or rather, development.

Appearances in Variola Virus.—Smears made from the vesicles and pustules of cases of variola show uniformly, and much more distinctly than vaccinia virus, small bipolar bacilli. When carefully stained, in a similar way to that recommended for vaccinia virus, these bacilli are very distinct and numerous. In the microphotograph of a variola

*Throughout this article I have put the word spore in quotation marks, since by it I mean one of the polar bodies that escapes from the involution oval shaped bacilli and grows into new bacilli, and not the involution form itself.

pustule smear, reproduced herewith, the outlines of most of the bacilli are poorly defined owing to the failure of photography to distinctly record lines depending mainly upon differences of refractility, such as surround the non-standing areas; but this is not

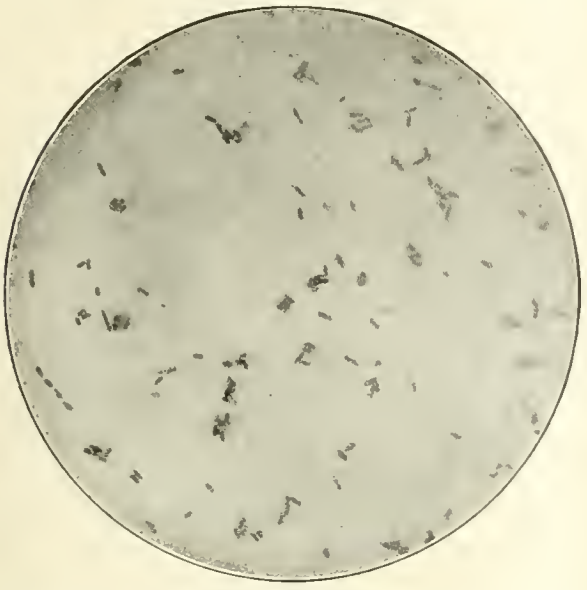

FIG. 3—Variola bacillus from culture on Loeffler's blood serum. Virus taken from pustule of S. A., a negro patient of the Kingston Avenue Hospital, at the height of a severe generalized variola eruption. Smear stained with alkaline methylene blue. Magnification 1650.

the case in direct observation of smears. As a case progresses to recovery, oval involution forms, similar to those of vaccinia virus, appear.

Cultures from Variola Virus.—Primary cultures from vesicles and pustules, made in limed bouillon (with or without hydrocele fluid) within 3 to 5 days show many of the small bipolar bacilli. Cultures made on Loeffler and regularly watered with limed-bouillon (as described in connection with vaccinia cultures) show within about ten days numerous low lying greyish colonies of very mucilagenous consistency.

Unlike the colonies of the vaccinia organism, developed under similar circumstances, there is but moderate tendency to subsequent liquefaction of the media, and the first few transplants usually refuse to grow on Loeffler unless it be "watered." After several generations, however, the organism will grow on plain Loeffler and will often partially digest it.

The appearance of the full grown bacillus from variola is very similar to that of the organism of vaccinia. In the microphotographs, actual differences seem very marked, owing mainly to different ages of the cultures used.

Cultures from Blood of Variola Case.—In one case, blood smears were examined at the height of the eruption and fever, and small bipolar bacilli were observed lying free in the serum and in about the same proportion as the leucocytes. It may be interesting to note that the latter had increased to about 24,000 per cubic millimeter, and were lymphocytes to the extent of about 50 per cent. Cultures made from the blood of this case gave exactly similar growths (by the same methods) as were obtained from the pustules.

Appearances in Varicella Virus.—The contents of the average varicella vesicle is usually very watery and organisms are correspondingly scarce. Yet every one from which a smear can be obtained, shows minute bipolar bacilli. The organisms are very numerous in smears made from severe cases. They resemble closely the bacilli of the variola vesicles.

Cultures from Varicella Virus.—Cultures from varicella vesicles, made and treated identically as those from vaccinia virus, give similar results. After two or three days in limed bouillon (with or without hydrocele) minute bipolar bacilli are numerous, and on solid media (Loeffler) "watered," as before, in about ten days a profuse development of grayish low lying mucilaginous colonies, which, in another 24 hours, liquefy the media. Replants from such liquefying colonies are very vigorous and grow very easily on plain Loeffler, liquefying it actively by the end of the first 24 hours.

The full grown bacillus from varicella cases is very similar to the vaccinia organism. In an epidemic of varicella this spring in a Brooklyn institution, smears were made of nasal and tonsillar mucus from three children who had been exposed to the contagion, and in two of the three cases bacilli exactly similar to the full grown varicella culture organisms were found. Both these children developed a varicella eruption two days later. Similar bacilli are uniformly present in the nasal mucus of active cases of varicella.

In the table which follows, the complete morphology of the organisms is given, as well as such differences between the three varieties as have been observed:

TABLE VI.—DETAILED CHARACTERISTICS OF THE THREE ORGANISMS COMPARED.

(Description applies to all except when it is stated otherwise).

I. MORPHOLOGY.

Vegetative Cells (a)

Medium: Loeffler blood-serum, wet daily with "enlivened" bouillon. *Temperature:* 37.5° C. *Age:* 7-10 days. *Form:* Long rods, quite variable in size—from 0.3 by 0.7 microns (as in virus smear) to about 0.6 by 3.5 microns (as in full development on Loeffler). Varicella organism is usually the longest. *Ends:* Rounded.

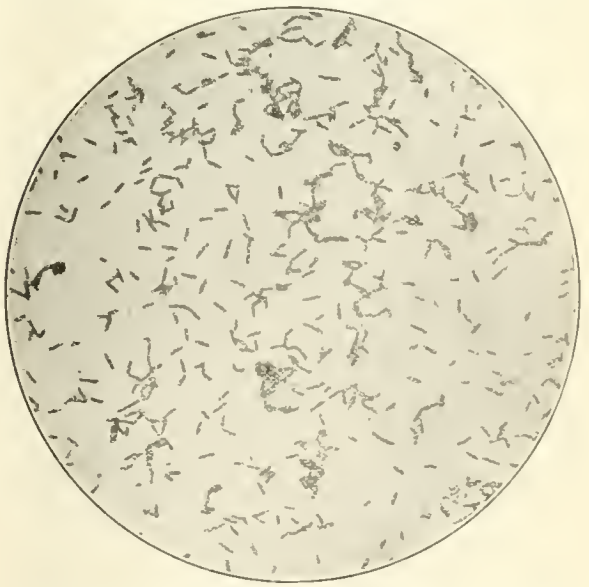

FIG. 4—Varicella bacillus. Primary culture from vesicle, 10 days on Loeffler. Stained by alkaline methylene blue. Magnification 1,650. This smear was made as soon as visible colonies developed, and just before organism began to "sporulate."

Arrangement: Small fluid-media forms—singly and in branching clumps; large solid media (aerobic) forms—commonly parallel and at acute angles (as diphtheria bacilli) sometimes in chains, especially the varicella bacillus.

Sporangia (b)

These involution forms appear in primary cultures, made as above, in about ten days; in replants in about three days. *Form:* Elliptical. *Size:* Slightly broader and shorter than fully developed bacilli. *Location of "Endospores":* Bipolar, sometimes unipolar. *"Endospores" (c)*

Form: Round; many, so soon as they escape, seem to divide and produce the minute bipolar form, as seen in the virus. *Size:* Round form, 0.3 microns; bipolar form, 0.3 by 0.7 microns (approximately). *Germination:* Bipolar, "spores" escape through rents in ends of cell wall.

Flagella (d)

Full grown bacilli, propagated in bouillon, are actively motile. The variola bacillus (full grown) does not develop active motion until after several generations in bouillon of a replant from primary solid media. Carefully stained by Gram's or Van Ermengen's method, a single short terminal flagellum may be seen.

Capsules (e)

Usually noticeable.

Staining (f)

Virus and vesicle smear forms, particularly, and those of primary cultures in "enlivened" bouillon are very difficult to stain, except at the poles. Full development forms stain easily with all the usual dyes. *Gram's:* Results vary somewhat with age of organisms; "spores" and polar areas are always positive.

2. Cultivation.

Loeffler's Blood Serum: Virus, vesicle, pustule (and, with variola—as found with the one case tried—blood, taken during the early stage of the eruption) plants, watered daily with "enlivened" bouillon, show, after 24-48 hours, the minute bipolar bacilli—usually there is no macroscopically visible growth. After 7-10 days, primary cultures usually show many round, glistening, greyish, low lying, viscid colonies. (I have seen a development appear, in a tube protected from drying out by a paraffined plug, as late as a month after sowing with vaccinia virus. Sometimes, when no macroscopic growth has appeared after a ten day incubation, a replant to a fresh tube will give prompt results) *Liquefaction:* This begins within 24 hours of the appearance of the viscid colonies described, and reaches its maximum within three days. *Replants:* If made from fully developed colonies of either the vaccinia or the varicella bacillus, replants on Loeffler usually produce abundant, flat, cretaceous growths, often wrinkled. Variola bacillus replant cultures, have, so far, invariably reproduced the original colony development, and usually show slight liquefaction of the surface of the media within three days. Vaccinia and varicella replants always produce liquefaction of nearly the entire medium. *Odor:* Distinct after liquefaction, especially in the cases of the vaccinia and the varicella organisms never putrefactive.

Bouillon: (limed, "enlivened") Primary cultures, during the first 48 hours, usually show no macroscopic change, but many minute bipolar bacilli may be found in the sediment. After 3-5 days these cultures often become cloudy, and show numerous bipolar bacilli of the small form, of intermediate size, and some of the full development. Replants from the cloudy cultures, and also replants from solid media (Loeffler) made in plain bouillon show diffuse clouding within 24 hours, or else, in the cases of the vaccinia and the varicella bacilli, a surface growth similar to the replant development described in connection with Loeffler's medium. Sometimes these two organisms will give the surface growth (without clouding of the bouillon) and sometimes a general clouding without the appearance of a scum. I have seen no surface development appear in the case of the variola bacillus.* In such transplants, the medium from which taken and the stage of development, seem to be the determining influence (with the vaccinia and varicella organisms) in respect to the form of growth in plain bouillon. The first few generations of the variola bacillus, replanted in bouillon, persist in the minute non-motile form but later develop, and continually reproduce, the large motile form. *Serum*, diluted with broth or water, effects a reduction of the variola bacillus (large form) to the minute non-motile form, when a transfer is made to it. The same may be effected in the cases of the vaccinia and the varicella bacilli (large forms) but is more difficult, since the large-bacillus form of growth tends to persist.

Nutrient Agar: Replants from profuse surface growth of the vaccinia and of the varicella bacilli sometimes show a growth similar to that which appears on Loeffler within 24 hours. The variola organism grows feebly or not at all, when so transferred.

3. Physical and Biochemical.

Gas Production: In bouillon containing 1 per cent. of dextrose, 48 hours, at 37.5°C. vaccinia bacillus: (2nd generation) produced no gas. Growth poor; variola bacillus: (8th generation) produced no gas. Growth poor. Varicella bacillus produced considerable gas.

Acid Production: In bouillon the growth of all three organisms (large forms) produce acid. In 48 hours the varicella bacillus, growing in 2 c.c. of this medium, developed acidity in it which required 0.07 c.c. of decinormal sodium hydroxide to neutralize.

Indol Production: In 0.5 per cent. Witte's peptone, after 72 hours at 37.5°C., the Salkowski test indicated a *feeble* production of indol by the vaccinia bacillus, a *very feeble* production by the variola bacillus, and a moderately large production by the varicella bacillus.

Vitality on Culture Media: All three organisms may be cultivated indefinitely under conditions described.

Drying: All three organisms are readily killed by drying.

Ferments: "Sporulating" forms liquefy Loeffler variola bacillus much less readily than the others.

*Since writing this, a slight surface growth on bouillon, of the variola bacillus, has been observed. It seems that the longer this organism is cultivated the nearer does its relationship become to the vaccinia organism.

TABLE VII.—COMPLEMENT FIXATION TESTS.

Serum Tested			Variola Antigen.		Vaccinia Antigen.		Varicella Antigen.

Filtration: Cultures of all three organisms at the sporulating stage passed through Berkefeld filter (No. 5) give a filtrate from which new cultures (replants) may be readily obtained, on media described.

4. Pathogenicity.

Work in connection with pathogenic properties of these organisms, and natural and artificial immunity to them, is incomplete and will be the subject of a later publication.

Agglutination Tests.—In examining the table of agglutination tests we note that the variola organism was agglutinated, within one hour, in variola sera dilutions as great as 1-160, while with all of the six normal controls practically no agglutination developed. The sera of the recently vaccinated showed considerably greater agglutinating power over this (the variola) organism than that of the average adult; the varicella sera were totally lacking in this power. With the animal sera the results were inconclusive.

The vaccinia organism was clumped even more markedly than that of variola by variola sera. This organism was most specifically clumped by the animal sera tested, as is seen in the table in the case of both the calf and the rabbits.

The varicella organism was irregularly affected by all except the varicella sera which, strange to say, were the only ones totally without influence upon it.

From the standpoint of the sera examined we find indication from the table that specific value can be attached to the agglutination test in the case of variola.

Also that, in the case of vaccinated animals, their sera have specific agglutinative power over the vaccinia organism.

Complement Fixation.—It was found that the growth from the surface of Loeffler serum, before peptonization of the media had begun, was unsuitable for antigenic purposes since no filtered extract could be obtained which would give an anticomplement unit. If, however, peptonization had commenced (and this, as stated, is coincident with the breaking out of "spores") a definite anticomplement unit was easily found.

The antigen in the case of each of the organisms was prepared as follows:

The growth from the slant surfaces of four Loeffler serum tubes (usual 4-in. size) organisms of respectively, 3, 5, 7, and 14 days' growth (replants), was washed into 8 c.c.'s of normal salt solution, sealed in a tube and heated for one hour at 68° C. It was then filtered through Berkefeld filter No. 5 and tested.

Anticomplement units in the sheep-rabbit-guinea-pig hemolytic system (bulk of test 0.5 c.c.), were found to be as follows:

Variola antigen	0.15
Vaccinia	0.05
Varicella	0.10

Therefore, according to the usual procedure, one-fourth of these anticomplement units, made up to be contained in 0.15 c.c., were used in the tests detailed in Table VII.

Reviewing the table mentioned, we note that the variola antigen gave strikingly specific results with its corresponding serum. (The results were the same when half the antigen unit was used.) This antigen gave negative results with practically all of eleven sera taken at random from normal adults, four of whom had been successfully vaccinated within three months. Of these four, however, one gave a (+ +) and two a (+) reaction. Negative results were also obtained with sera from two children convalescent from varicella.* Results with animal sera are seen not to have been distinctive—possibly through failure to properly control the known anticomplementary action of such sera.

The vaccinia antigen gave irregular results with the normal adults, with the exception of those recently successfully vaccinated. The negative results, when tested with variola sera, are most interesting as contributing to the establishment of distinctions between the organisms in question. (The three cases of variola from which the sera came had never been vaccinated.)

Except, perhaps, with that from the calf in the case of the vaccinia antigen, the results with animal sera were generally unsatisfactory.

The varicella antigen, curiously enough, while it gave negative results with both variola and varicella sera, gave positive tests with most of the normal adult sera tried, as it did likewise with the animal sera.

Examining the same table for the results obtained with specific sera we note that the only clean cut results were from the variola sera. In the case of the others (with the exception of the inexplicable instance of the varicella sera) various plausible interpretations will suggest themselves to the reader.

Thanks are due to Dr. W. T. Cannon, resident physician, in charge of the Kingston Avenue Hospital, for opportunities to get material from cases of variola; to Dr. F. S. Fielder, in charge of the Department of Health Vaccine Laboratory, for blood from rabbits used to produce "seed" vaccine; to Dr. G. W. White, in charge of the Otisville Sanatorium Laboratory, for calf serum. Also to Dr. H. A. Reque, for material from varicella cases; to Dr. F. M. Sharpe, Dr. J. C. Kennedy, and to many other Brooklyn physicians, for the same.

140 Clinton Street.

A PRACTICAL METHOD OF TREATMENT FOR "INOPERABLE" CANCER OF THE BREAST.†

By CHARLES WILLIAM STROBELL, M.D.,

NEW YORK.

VISITING GYNECOLOGIST, WEST SIDE GERMAN DISPENSARY AND HOSPITAL.

The purpose of this paper is to make known to the medical profession a method of removing the cancerous breast, which, as regards results, has as yet shown no subsequent remanifestation or recurrence of the disease within the limits of the operated area. Work and observation along this line now cover a period of seventeen years—my first operation having been performed in October, 1898. In all, sixteen patients have undergone the operation. The first eight cases were reported in the *American Journal of Surgery*, Nov., 1912. With two exceptions, the eight previously unreported cases herewith presented were operated upon at the Memorial Hospital for the treatment of cancer and allied diseases; the two exceptions at the West Side German Dispensary-Hospital.

The technique has undergone important modifications since 1912. It is earnestly hoped that the

*Results from these sera are offered with reserve, since they were negative throughout the series of tests for some unknown reason.

†Read by invitation, at Newark, N. J., January 25, 1916, before the sections of Surgery, Gynaecology and Obstetrics; under the ausnices of the section on Gynaecology and Obstetrics, of the Academy of Medicine of Northern New Jersey.

method will not be brought into disrepute through inadequate technical preparation; it is a surgeon's task; wherefore without the especial qualifications, it were better not undertaken.

Absolute removal of all cancer cells has been, and still is, the goal of all progressive surgical technique, with the result of gradually improving statistics. These statistics are, however, still far from holding out hope of ultimate absolute reliability along purely surgical lines, limits having been reached which may not safely be transgressed. The fatal defect lies in the inability of the operator to know at the termination of the operation whether or not all cancer cells are included in the removed tissue. Neither macroscopic nor microscopic examination permits of such a conclusion. Thus the only reliable proof of the removal of all cancerous cells in any operative area lies in the hazardous test of time.

These considerations, especially the frequent recurrences in the line of incision, have led me to proceed in an entirely different direction in the hope of avoiding local recurrence; and the striking fact of non-recurrence in the sixteen patients operated upon to date, indicates that there is a sound basis underlying the method. Yet I am not on that account here urging this treatment in the place of the usual surgical removal of mammary cancer in operable cases. Neither is it my intention to claim priority in the use of any of the agents employed in this work, or of any combination of them; the knowledge of their nature and use is common, and "old as the hills." Starting out with well-founded convictions as to the cause of local recurrence, following cancer operations in general, my idea was to develop in accordance therewith a simple and practical technique for the removal of the cancerous breast, to be, if possible, as extensive in scope as is the knife, but with the added advantage of an inflammatory reaction in the floor of the wound capable of destroying infected cells ordinarily responsible for local recurrence; also to accomplish this without possible further dissemination of the disease by manipulation or incision.

Theoretical Basis. — Theoretically, proliferating cancer cells scattered about in the tissues, comprising the floor of the usual amputation wound and commonly responsible for recurrence, are destroyed by a chemically induced inflammatory reaction attendant upon the formation of a "line of demarcation." This intense inflammatory reaction, penetrating deeply these floor tissues, constitutes a protective process, absent in other methods. The phenomena are:

1. Destruction by chemicals of the entire cancerous breast and isolated cancer cells, *in situ*.
2. Absolute avoidance of manipulative displacement onward of loose proliferating cells through vascular channels beyond the limits of the operative field.
3. Leisurely and safe necrotization of the condemned tissues to any necessary extent.
4. Phagocytic walling-off process of offense and defense, sealing all vascular channels preparatory to nature's own amputation at the line of demarcation.
5. Intense inflammatory reaction within the zone of tissues underlying the terminal or separated layer of necrotized tissue, followed by vigorous healthy granulations.
6. Regression, in varying degree, of enlarged axillary nodes.
7. Repair always vigorous and rapid, facilitated by autoplastic skin grafts, and resulting in a perfectly functionating, freely movable skin surface.
8. Unimpaired arm movement.
9. Absence of recurrence in the operated area.

This process is lethal to cells in that the active chemical agent is absorbed by the dormant tissues upon which it is spread. Cancer cells are not disturbed, but perish where they are overtaken. Avoidance of manipulation is ideal, as the destruction and daily removal of layers of devitalized tissues proceeds from above downward—the last layer being removed by natural processes. Leisurely the operation certainly is, as there is never occasion for haste.

Pain in the breast tissues in some degree there may be both before and during removal. Pain in the surrounding skin there would be, should one fail to protect the outlying or surrounding surfaces from the action of fluids draining away from under the dressings. This latter is, however, avoidable, while pain in the operative field is readily controlled. The method is free from shock, and therefore a perfectly safe operative procedure. It is particularly well borne by those well advanced in years, and by poor operative risks in general.

The *inflammatory reaction* is the key to the situation and solves the problem of local recurrence. The "walling-off" by an intense leucocytic exudate obviates the sudden severance and consequent exposure of defenseless tissue to possible reinfection.

Diminution of Axillary Nodes.—Where axillary lymph nodes are enlarged and there is no evidence of mediastinal involvement, as shown by a Roentgenogram, the nodes may be simply inflammatory, in which case they tend to rapid disappearance. When, however, the nodes have undergone hyperplastic, or fibrous changes, neither rapid nor total retrogression could of course be expected. My second case—still living—has carried such a node, unchanged, for nine years.

It is, of course, generally recognized that when the axillary nodes are invaded by cancer the prognosis for any form of treatment becomes very unfavorable. Greenough (*Annals of Surg.*, Vol. 46) reports that of 236 cases with palpable axillary nodes, only 12 per cent. were cured by operation, while of 275 similar cases, Finsterer (*Zeit. f. Chir.*, bd. 89) reports only 4.3 per cent. cured. With involvement of supraclavicular nodes, the condition is much more unfavorable. When the axillary nodes alone are involved, the chemical removal of such nodes cannot be claimed to be as thorough or radical in its operation as the dissection of the axilla by the knife. When both axillary and supraclavicular nodes are involved, the patient will probably sooner or later succumb to the coincident internal metastases, and the removal of nodes would not materially influence the prognosis. This at least is my observation.

Indications for Chemical Operation.—The exact scope of the applicability of the chemical operation is as yet difficult to determine. In a general way, to a believer in the "lymphatic permeation" theory of Handley regarding the mode of dissemination of cancer, it would seem reasonable to suppose that the "microscopic growing edge" could, with more certainty, be overtaken by the penetrating destructive action of zinc chloride and subsequent inflammatory reaction than by methods not accompanied by such phenomena.

At present, it is at least clear that the operation

has a definite field in the several groups of cases classed as inoperable. Particularly so in:

1. Cases of advanced inoperable carcinoma in which the local condition is intolerable to the patient and attendants by reason of ulceration, hemorrhage, suppuration, necrosis, fetor, and pain. Here the chemical operation speedily changes the intolerable condition to one of wholesomeness and comfort and restores the patient to her home and friends. (See Figs. 2 and 3.)

2. Cases of advanced or of *operable* carcinoma in which there exists a contraindication to operation by reason of general debility, valvular disease of the heart, or nephritis.

3. Cases of advanced carcinoma with invasion of axillary and supraclavicular nodes, in which experience shows that postoperative recurrence is practically certain.

In the above groups of cases the results of chemical removal have been so much better than might be expected that I naturally feel inclined to employ the method in all breast cases in which the outcome of surgical removal is distinctly unfavorable. Only inoperable cases have thus far been treated.

As to recurrence of the disease, within the limits of the operated area, following chemical removal, it has yet to be noted.

Active agents employed in the operation are:

Potassium hydroxide (KOH) U. S. P., long crayons, employed only in the first stage, or stage of denudation. The substance absorbs water from the tissues and diffuses quickly. Its effect is to disorganize and liquefy tissues, which it does to a considerable distance.

Zinc Chloride Compound.—

℞. Zinci chloride, U. S. P., ℥vi.
Sanguinariæ radicis, pulv., ℥ii.
Carbonis salicis albæ, pulv., ℥i.

M. Employed only in the second stage for the destruction of gross breast tissue.

The action of this compound may be fittingly designated :: the chemical drive. Zinc chloride is a safe escharotic in this operation, in that it is not absorbed by the system to the extent of reaching vital parts. Its "drive," so far as observed, is about three-fourths of an inch in depth. The outer third of this "driven" tissue dies a rapid death, becomes hard and leathery, and may be removed; while the inner two-thirds successfully resists its attack. This remaining two-thirds undergoes inflammatory reaction, theoretically fatal to cells of lower degree of vitality than the normal.

The compound is prepared by trituration in a Wedgewood mortar. The sanguinaria—a vegetable escharotic and adjuvant—is combined with the given quantity of zinc, to make a mixture of the consistence of vaseline, or cold cream, when water is added. Powdered willow charcoal is added to blacken the mixture, which serves to identify it. The coloring of the mixture is important, since thus is made practicable the strict confinement of the active agent within prescribed limits, which is absolutely essential to a painless operation. Wherever the least "speck" of this black mixture settles and is allowed to remain on the adjacent skin, there it will destroy tissue and cause needless pain.

Armamentarium.—A well-lighted operating room is essential. Besides the anesthetist, two assistants will be required; long crayons of KOH; a wedgewood mortar, containing the zinc compound ready for applications; a half dozen hemostatic forceps; bandage shears, scissors, and scalpel; tincture of iodine; steel spatulum; two six-inch thumb forceps; ten-yard spool of surgeons' zinc oxide adhesive plaster; good supply of gauze sponges, 6 x 6 inches; and 2-inch canton flannel strips; one pound of absorbent cotton; rubber gloves, gowns, etc. Protective compound:

℞. Boracic acid, 2 parts.
Starch, 20 parts.
Zinc oxide, 20 parts.
White vaseline, 58 parts.

Anesthesia is employed in the first and third stages only, according to the case. It may be primary, general, or local.

If primary, the production of analgesia, amnesia, and anociassociation alone is aimed at. Agents thus used are morphine with hyoscine or scopolamine, combined or not, with inhalants; if general, morphine, followed in a half hour with ether, or nitrous oxide gas and oxygen; if local, only by nerve blocking at the spinal roots.

Technique of primary anesthesia: One and a half hours before starting the operation, grain 1/128 of hyoscine hydrobromate, grain 1/128 of scopolamine hydrobromate, and grain ¼ of morphine sulphate (or gr. 1/128 of scopolamine hydropbromate, and gr. ¼ of morphine sulphate) are administered hypodermically.

The operation starts one hour and thirty minutes after the hyoscine-morphine injection, coincidently with the administration of inhalants. As the work proceeds, the patient is gently aroused from time to time by the anesthetist, the ability of the patient to respond being the guide to dosage.

Operative Plan.—First stage, denudation; second stage, removal; third stage, skin-grafting; fourth stage (occasional only), lymphangectomy, radium, *x*-rays.

The object to be accomplished in the *first stage* of the operation is the destruction and removal of all skin layers overlying the mammary gland, together with its attached underlying fascia, and including the nipple structures.

The object aimed at in the *second stage* is the destruction and removal of all mammary and adjacent infected tissues from the midsternal and midaxillary lines, horizontally, and from the second to the seventh ribs, vertically. This removal includes all accessible fascial structures and the major portion of the great pectoral muscle. It may also if required include the costal periosteum.

The object of the *third stage* is to facilitate repair of the granulating surface by grafting it with healthy skin taken from the patient's thigh. This hastens convalescence and insures a functionating, freely movable skin. It also minimizes contractures.

Persistence of enlarged axillary lymph nodes at the conclusion of the healing process constitutes a *fourth stage* in which these glands may be treated by physical methods, or dissected out *en masse*. (The rôle of the lymph nodes in this operation has not yet been worked out. My experience is that in a large percentage of cases they regress in varying degree, or remain stationary without further manifestation.)

Preliminary Precaution.—A limiting or boundary line should be drawn on the skin with moistened lunar caustic twenty-four hours before the operation, following as closely as possible the circumferential basal outline of the breast. This, by then, blackened line must not be crossed the following day in the process of denudation, as it provides a

margin of safety for the spreading action of the chemical in the second stage, wherein the diameters of the field are extended. Wide removal of the skin is always indicated.

Operative Technique.—First stage, denudation.—The operator may begin his work immediately the inhalation of gas and oxygen or ether is started. The surrounding skin surface is first protected from the action of the chemical by a liberal application of the protective compound.

The destructive agent employed at this stage is potassium hydroxide, which liquefies tissues more or less rapidly. The commercial long crayons are used, the holding end being wrapped about with gauze for protection of the operator's hand. The free end of the crayon is dipped in water and made to pass gently to and fro over the skin surface, within the limits previously marked. Any liquid excess of the potassium hydroxide must be constantly wiped away as it forms, to prevent its contact with the skin outside the limiting silver line. Sponges of absorbent cotton, dipped in water and wrung out nearly dry, are best for this purpose. Soon, a multitude of small brownish necrotic spots appear all over the breast; these later coalesce until the entire surface is of a light brown color. The epithelial layers then successively peel off. Later, the necrosis extends to the fascia. Openings appear here and there, through which can be seen the fat lobules. With the removal of the fascia is encountered the network of superficial mammary veins. As the walls of these veins are destroyed, venous oozing begins, but this is easily controlled by clamping and pressure.

The removal of the skin fascia nipple, and its areola accomplished, the remaining portion of the breast presents as a mass of fat lobules, exhibiting the characteristic concentric arrangement of the mammary gland with its radiating vertical septa. This process occupies on an average about the space of an hour, varying with the texture of the skin and the size of the breast.

The Second Stage.—The second stage, or stage of *removal* of the mammary gland proper, may be begun, if primary anesthesia has been employed, when denudation is completed and before the patient leaves the table. *If, however, general anesthesia has been employed, the application of the zinc compound would better be delayed for six hours, or until there is certainty that the dressings will not be shifted to adjacent skin surfaces, where they would cause discomfort, by the restlessness of the patient.* In either case, the protective compound is removed, and strips of cotton cloth, rather thinly spread with the zinc compound, are applied to the breast. Care must be taken to have the zinc compound of just the right consistence, or the agent will "run" over the adjacent skin and cause severe pain. The zinc compound must be kept absolutely within the bounds set for it, and for this reason the operation is best done at hospitals where the nurses are familiar with the work. Proceeding spirally from the base upward, the zinc-cotton strips are then securely fastened into position by inch-wide tapes of surgeon's adhesive plaster, forming a cap when completed. At the expiration of twenty-four hours the plaster and zinc cap is lifted off, and the layer of devitalized tissue removed by careful dissection. In doing this the operator must be mindful not to traumatize the living and sensitive tissue beneath, or pain and hemorrhage will follow. Removal of the mummified layer completed, a fresh application of the active agent is made, as well as of the skin protective, and so on from day to day until the deep fascia is removed and the fibers of the pectoralis major are exposed. Upon this, the final application of the active agent is made for from 24 to 48 hours, according to indications.

This last layer of devitalized tissue is not to be disturbed, but is, in a variable period of time, cast off by an intense reactive exudative inflammation, which extends deeply into the underlying tissues and forms a line of demarcation. The resulting slough leaves a finely granulating level area which discharges a profuse lymphorrheic exudate (see Fig. 1). Febrile disturbances accompany the operation throughout, but more especially so during the separation of the final layer or devitalized tissue, when the temperature, pulse, and respiratory fluctuations attain the maximum. Fluids forming under the last layer of the slough must be given early and free exit by means of dependent drainage openings, mainly approximating the axillary edge. The amount of absorption is never alarming. Throughout this second stage the nursing is of the utmost importance *both by day and by night.* The indication is best met by the application of absorbent cotton sponges, changed hourly, to prevent the zinc compound drainage fluids from running down over the axillary edge, and coming in contact with the adjacent skin. Frequent bathing of this skin area is of greatest benefit. The nurse should at all times be sure that the dressings are absolutely in place and not allowed to shift from their moorings. Also she must scrupulously remove and keep off any black "speck" or stain from the skin outside the line of demarcation. All these special precautions may, of course, be discontinued when the final zinc application is removed.

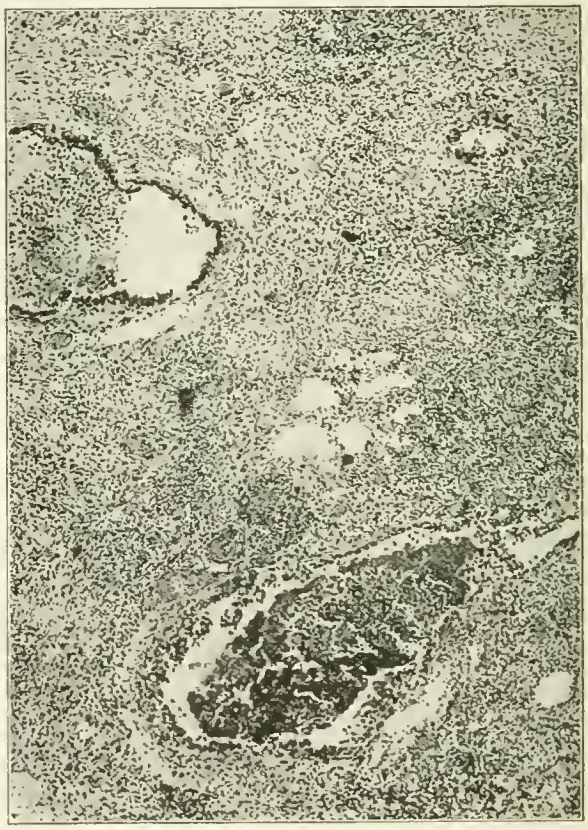

FIG. 1.—Character of the tissue reaction in the operated area; thrombosis of vessels with rich polynuclear leucocytic exudate into stroma and gland alveoli.

Irregular loosening or separation of the slough will cause some discomfort, especially from the resisting nerve fibers. Prompt removal of loosening portions is best in some cases; in others, it is better to support them and allow all to come away *en masse*. Pain manifesting itself at any stage of the operation is always readily controlled by the judicious employment of morphine or codeine. Usually none is requred.

Much might be written on the technique of this stage of the operation. In the daily removal of devitalized tissues good judgment is required to know just how deep to cut, and in what direction, in order to avoid pain and hemorrhage. Danger signals must be respected, and these things can come only with experience and observation. As to hemostasis, tincture of iodine has proved to be of greatest service. It is an ideal antiseptic as well, and should be applied upon the slightest appearance of color. For any obstinate oozing, such as may occur in the removal of indurated tumor tissues or when encountered in the soft abscess walls, or hematomata, the most reliable hemostatic is the zinc chloride compound, applied to the site on a small patch of cotton cloth and moderately compressed by means of a wad of absorbent cotton, for a short space of time. The action of this agent thus quickly controls the situation. The application of hemostatic forceps is not very useful in the stage of removal, owing to the friability of the devitalized tissues, yet occasions will arise where it can best control the situation.

During the period of separation or sloughing, and up to the time of skin grafting, a cerate composed of: Pinus canadensis, ℥i; white wax and zinc oxide, of each, ℥iij, and white vaseline, ℥xii, is spread thickly on a square of cotton cloth, large enough to cover the wound and three inches beyond in all directions and applied. This dressing should be changed every eight hours. No other will be required throughout.

At times it will be desirable to facilitate separation of the slough when the vitality is low and repair processes slow, by the application of dry or moist heat. This is most readily and neatly accomplished by the employment of an electric pad 6 x 8 inches, with or without an interposed wet compress.

Skin Grafting.—The third stage consists of covering the granulating area with skin grafts from the patient's thigh, by the well-known method of Thiersch. These thin tissue paper-like grafts should be immediately transferred to the waiting breast surface. They should overlap the edges of the wound. The grafts are covered with a sheet of asceptic rubber tissue, and over this several layers of gauze, all strapped securely into position.

This dressing need not be changed for a week, when the grafts will all be found to have "taken." The thigh is similarly dressed, but these dressings are renewed every second day. The thigh surface speedily heels over and causes no inconvenience. The new skin soon becomes as freely movable as on the back of the hand, and functionates perfectly. (See Fig. 2.) A dusting powder of boracic acid, following the daily cleansing or dressing, is the best treatment for some time after the dismissal of the patient.

Advances will continue to be slow, from the very nature of the work. However, that progress has been made is evidenced by the fact that at the Memorial Cancer Hospital, where for the past eighteen months this method has been under observation, it has been conceded that the author's chemical operation has a definite field in surgically inoperable cancer of the breast.

The following six case reports from the records of the Memorial Cancer Hospital, as also this paper, are published with the approval of the committee on publications, Drs. James Ewing, Wm. B. Coley, and Richard Weil.

Case I.—Mrs. C. J., age 79, widow. Admitted May 20, 1915. Ad. No. 21418. Chief complaint, tumor of left breast. Grandmother and aunt died of cancer. Present illness began two years ago. First noticed that the left breast became swollen, but no pain. About a year ago, consulted physician, who told her that there was a large lump in her breast. Shortly afterward she noticed retraction of the left nipple and some discharge therefrom. About six months ago, noticed some blisters appearing on the skin of the breast, which broke down, leaving a yellowish scab. This had continued up to the time of admission, when it involved the entire breast.

Status Praesens: There is some discharge exuding from the ulcerating surface. *Clinical Diagnosis:* Cancer of the breast. *Pathological report on specimen from lymph node:* Metastatic alveolar carcinoma. (Ewing.) *X-ray of chest:* Glands of hilum of lung much enlarged and represent probable metastasis (Holding).

Operated upon by chemical method, May 27. Operation completed and ready for skin grafting, June 14. Postponed. Patient died a week later of uremia. The autopsy showed an advanced chronic interstitial nephritis. The temperature range from time of admission was between normal and 102°; pulse between normal and 100; respirations between normal and 40.

Notation.—The operation was done to relieve an intolerable necrotic local condition. The influence of the operation in hastening death is problematical. For the sake of statistics, had the renal condition been known, the operation would better not have been done, as it was only a matter of days, at the best.—(Author.)

Case II.—Mrs. E. T., widow, age 64. Admitted September 11, 1914. Ad. No. 21603. Chief complaint. —Tumor of the breast. Mother died of cancer of breast. She had an operation for tumor of right breast at 18; and one for tumor of left breast at 28. Present illness began fifteen years ago with small nodule in region of left nipple. The nodule remained small until three months prior to admission. It was tender but not painful. Two months ago noticed a large lump in the breast; pain became more constant, nipple retracted, reddened. General condition of patient good.

Status Praesens: Left breast the seat of a large, irregular, indurated growth, the size of an orange, not very firmly attached to the fascia; skin adherent, nipple retracted. (Axillary nodes were enlarged. December 18, 1915. C. W. S.) *Patholigical report:* Alveolar carcinoma; mucoid changes in certain areas (Ewing). No X-ray examination of chest was made before operation.

Operated upon by chemical method September 12, 1915; skin grafting, September 28. Discharged, October 8, 1915. Temperature fluctuations between normal and 101°; pulse, normal and 116; respirations between normal and 24.

Notation.—The breast was removed, together with half an inch in thickness of the pectoral muscle. The resulting smooth healthy granulating surface was covered with skin transplants from the thigh. Good operative results; fine movable functionating skin surface. This patient is alive and without sign of local recurrence. *X*-ray examination of chest, taken February 3, 1916, shows enlarged glands in right side of chest extending from mediastinum out into lung tissue, apparently along the bronchial tube.—(Holding.)

Case III.—E. C., age 59. Admitted May 21, 1915. Ad No. 22296. Chief complaint.—Ulcerated tumor of the right breast. Trouble began about twelve years ago, when a lump the size of a hickory-nut was noticed above the right breast. This gave no trouble for nine years, remaining the same size, movable, not tender

and not painful. Three years ago this nodule began to grow rapidly larger; the skin over it became retracted, puckered (pigskin), and pain and tenderness were first noticed. One year later, the skin over the tumor broke down, and the ulcerated area has since increased in size until it is 4 x 3 inches in diameter. There was never any discharge from this nipple. There is no history of injury to the breast. Past and family history, not important. Constant excruciating pain for past two years.

Status Praesens: The upper inner quadrant of the right breast is the seat of the disease. Ulcerated area involves half of the breast. It is above the main mass of the mammary tissues. Edge, hard and elevated; base of ulcer is gray; purulent discharge, with foul odor. There is a deep contraction furrow between the breast and anterior axillary fold. There are no palpable axillary nodes. Pectoral gland at margin of breast, distinctly involved. Very corpulent female; left leg shorter than right from old fracture of femur, which is constantly painful. There is a pigmented eruption over the upper abdomen and lower chest. X-ray shows probable extensive metastasis in the chest (Holding).

Clinical diagnosis, based upon physical examination, —carcinoma of breast with metastasis in chest. *Pathological diagnosis:* Alveolar carcinoma.

Operated upon by chemical method, June 3. Skin grafted, June 30, 1915. Temperature range between normal and 101°; pulse between normal and 100 respiration between normal and 24. Discharged, August 1, 1915.

Notation.—The patient presented a very bad physical condition generally. There was constant sciatic neuralgia at and above the site of fracture—almost helplessly crippled. Right brachial neuritis streaking down into arm and breast complicated the far-advanced condition, which was absolutely inoperable surgically. Some avoidable pain was encountered during the removal. The breast was removed along with a half-inch layer of pectoral muscle and a large pectoral node. Later, small tubercles appeared an inch beyond the inner border in the skin. These were destroyed with KOH. The patient made a good recovery, and is well at this time of writing. The new skin surface is in fine condition. X-ray examination of chest, taken January 17, 1916, shows adventitious tissue in mediastinum, very marked on the right side. No metastases in lung parenchyma.—(Holding.) This operation was done at the request of the medical staff, for a demonstration of the method, the case being surgically inoperable. A pectoral node the size of a cherry persists.

Case IV.—Mrs. R., age 42, married. Admitted August 12, 1915. Discharged September 2, 1915. Admittance No. 22384. Chief complaint, tumor of right breast. Twelve months ago, patient first noticed a bloody discharge from the nipple. Several hard lumps developed around the nipple, and she experienced occasional sharp darting pains. The discharge continued and became more profuse in the later months. No other history of cancer in the family. The patient had a tumor of the right leg, which was removed at operation eight years ago. It was pronounced sarcoma. It recurred, broke down, and finally healed, giving no further trouble. Three months following the operation on her leg, an abscess in her left side (flank) developed. This was opened, drained, and healed.

Status Praesens: Thorax; left breast normal; right breast has nodules in lower outer quadrant, skin slighly involved, nodules hard. No X-ray of chest taken. Clinical diagnosis of carcinoma by five General Memorial surgeons. No pathological examination made.

Operation by the chemical method, August 12, 1915. Skin grafting was done August 26, 1915. Temperature fluctuations from normal to 101°; respirations from normal to 24; pulse from normal to 104.
